Abstract. Research of the geophysical electromagnetic phenomena with seismic activity is important for hazard-resistant strategy. Many papers which indicate the probable existence of geophysical electromagnetic phenomena associated with earthquakes are reported frequently. Anomalous propagation in the radio waves sometimes occurred around the same time of earthquakes. In previous paper, authors proposed a new concept to estimate the relation between earthquakes and anomalous line-of-sight propagation in VHF band by statistical approach. Event probability of the anomalous line-of-sight propagation increased just a few days prior to earthquakes. In this paper, we investigate a new relationship between anomalous fluctuations in the radio waves, which propagated from line-of-sight region, and occurrences of earthquake by using statistical analysis. Monitoring the strength of radio waves and detecting the anomalous fluctuations by using a new original method, we can obtain the high probability which indicates a possibility of association between the anomalous propagation and occurrences of earthquake. After the stochastic consideration, we can find out that the anomalous fluctuations sometimes appear one day prior to earthquakes near the wave propagation path.

1 Introduction

There is a probable existence of some relations between earthquakes and electromagnetic phenomena in a global scale. Research of the relationship between both is very important for a country with frequent earthquakes, likes Japan. There are many reports about geophysical electromagnetic phenomena associated with earthquakes. Geophysical electromagnetic phenomena can be observable by using electromagnetic wave propagation. Almost reports on the geophysical electromagnetic phenomena are classified into two groups, direct observations (Gokhberg et al., 1982; Smith et al., 1990; Hayakawa et al. 1996) or indirect observations (Fujiwara et al., 2004; Hayakawa et al., 2010).

In indirect observations, radio wave propagation is monitored for investigating the geophysical electromagnetic phenomena. The target radio waves are almost in VLF and VHF bands. Anomalous perturbation at the bottom of ionosphere can be monitored by measuring the VLF radio waves propagation. An anomaly in ionosphere appeared a few weeks prior to earthquake associated with it (Muto et al., 2009; Chakrabarti et al., 2010). Especially, some anomalies in signal amplitude and phase around sunrise and sunset times appeared a few days prior to the Kobe Japan earthquake, which occurred on 17th January 1995 (Molchanov and Hayakawa, 2007).
The other hand, there are many papers which report anomalous propagation in the VHF band waves from over-horizon broadcasting stations (Yonaiguchi et al., 2007). Yasuda et al. (Yasuda et al., 2009) reported that the anomalous propagation associated with earthquake occurred in the troposphere, and the anomaly affected the propagation path more 100km or so away.

The purpose of our research is to find out any relation between occurrences of earthquake and anomalous line-of-sight propagation in the VHF band. We have been observed broadcasting radio waves from line-of-sight region for several years. In the previous paper (Motojima and Haga, 2014), we reported that there was a possibility of association between the anomalous propagation and earthquakes by using the statistical analysis, in which we proposed an original estimation method of probability. As the results of stochastic analysis, earthquakes occurred after anomalous propagation were characterized by magnitude $M \geq 4.5$ near the propagation path.

In this paper we propose a new detection procedure of anomalous propagation for stochastic consideration. In the new method, the fluctuations are derived from the strength of radio wave by using wavelet analysis method. As the result of new method, we can get the high probability which indicates a possibility of association between earthquakes and anomalous propagation.

2 Anomalous line-of-sight propagation in the radio waves

The purpose of this paper is to discover any relationship between anomalous fluctuations in the line-of-sight radio propagation and occurrences of earthquake. We set up an observatory of radio waves at Kiryu Japan ($36^\circ 25'26''N, 139^\circ 20'58''E$), which is located about 90km north from Tokyo. The system structure and features was described in previous paper (Motojima and Haga, 2014). The radio wave observatory can provide the data of monitoring wave strength. Some dozens of waves in VHF and UHF bands can be monitored by our observatory. In this paper some representative radio waves are analyzed and discussed in detail. The transmitter stations, path lengths from transmitting station to receiving station, names of broadcast station and frequencies are listed as Table 1. Map position of the observatory, radio transmitter stations and wave propagation paths are described in Fig. 1. Black diamond is the observatory, sold black circles are the transmitting stations. Dashed lines show the wave propagation paths.

In most anomalies the fluctuations are occurred simultaneously in the multiple waves. Figure 2 shows an example of synchronism detection of anomalous fluctuation in the line-of-sight radio wave propagation. Figure 2 is the observational result on 3rd March 2015 in the multidirectional broadcasting waves, which were incoming from three transmitter stations — Tokyo-tower, Miyama and Hiranohara stations — as shown in Fig. 1. Each black solid line indicates the received signal strength. Each green line indicates mean value ($m$). Two blue lines mean an upper limit of ordinary propagation ($m + 3\sigma$) and a lower limit of it ($m - 3\sigma$), they were statistically derived from the long term observational data, from 2012 to 2015.

In each broadcasting wave, simultaneous anomalous fluctuation occurred at the same time: from 6 p.m. to 8 p.m. on 3rd May 2015. The wave from Miyama station showed most obvious anomaly, which is indicated in red dashed circles. First anomaly appeared in the predawn hours, then simultaneous anomaly occurred after sunset and was lasting until 11 p.m. An earthquake
happened subsequent to these anomalous fluctuations in a few hours later. It occurred at 23:30 LT on 3rd May 2015, 4.7 magnitude earthquake, centered in northern Kanto Plain (36°25′26″N, 139°20′58″E). These anomalous fluctuations might be the precursor of the earthquake.

3 Wavelet analysis of received radio waves

In the previous paper, we adopted a criteria based on signal strength level as decision for detecting anomalous propagation. Received signal strength beyond \((m + 3\sigma)\) or \((m - 3\sigma)\) was regarded as anomalous data, they were the detection thresholds. However, propagated radio signal is influenced by climatic phenomena. Climatic phenomena make frequently anomalous level of received wave strength associated without earthquake. To avoid the influence of level variation, we adopt the wavelet analysis of temporal variation in received radio waves. For the purpose, operating procedure of data, that is received radio wave strength, noted as follows.

1. Calculation of mean \(m\) and standard deviation \(\sigma\)

Radio wave propagation is affected by daily variation, because sunlight promotes atmospheric convection. The atmospheric convection decreases in the difference of atmospheric refractivity between upper and lower atmosphere. Under normal condition, therefore, signal strength in daytime is slightly weak and stable, in night time signal strength is slightly strong and unstable. In order to take away that daily variation, received data is normalized separately each time slot of a day. In our procedure, a day is divided into 288 time slots of five minutes, \(0:00 \sim 0:05\), \(0:05 \sim 0:10\), \(23:55 \sim 24:00\) and the data is normalized separately each time slot. Mean value \(m\) and standard deviation \(\sigma\) of each time slot are derived through the whole observation period, about three years. Therefore, 288 mean values \(m_i\) and 288 standard deviations \(\sigma_i\) are calculated for \(i = 1, 2, \cdots, 288\).

2. Normalized data of received wave strength

In order to detect anomalous fluctuation, normalized data is calculated from the mean of each time slot \(m_i\) in units of the standard deviation of each time slot \(\sigma_i\), as following equation.

\[
Normalized \ data \ x = \frac{\text{(Received signal data)} - (\text{Mean value} \ m_i \ \text{of corresponding time slot } i)}{\text{Standard deviation} \ \sigma_i \ \text{of the corresponding time slot } i} \quad (i = 1, 2, \cdots, 288)
\]

Equation (1) provides the corrected deviation free from the influence of daily variation.

3. Wavelet transformation
Wavelet transform of the normalized data $x$ is taken as the continuous wavelet transform (CWT). Wavelet coefficients $W(b,a)$ is given as following.

$$W(b,a) = \frac{1}{\sqrt{a}} \int_{-\infty}^{+\infty} \psi^*(\frac{t-b}{a}) x(t) dt$$

(2)

where $a$ is scale and $b$ is translational value, $x(t)$ is the normalized data. The $\psi^*$ is the complex conjugate function of Morlet mother wavelet as shown below.

$$\psi(t) = \frac{1}{\sqrt{\pi \lambda}} exp(j\omega t) exp\left(-\frac{t^2}{\lambda}\right), \quad \omega = \pi \sqrt{\frac{2}{\ln(2)}}$$

(3)

The wavelet coefficients are complex number because the Morlet wavelet is complex number. Then, we take absolute value of the wavelet coefficients.

4. Extraction of larger wavelet coefficients

Larger data in the top of 0.08% are extracted from the whole data of absolute wavelet coefficients. When a sequential larger coefficients appear in a few hours, we recognized the data as an anomalous fluctuation.

Figure 3 is an example of wavelet coefficients. Horizontal dashed line means the threshold level, which was determined by the number of larger data. The wavelet coefficients exceeded the threshold level three times from 14:42 to 21:16 LT on 12th Nov. 2012. Duration time of the exceeded wavelet coefficients was 6 hours and 34 minutes. We regarded it as occurrence of anomalous fluctuation.

4 Stochastic consideration between anomalous fluctuation and occurrence of earthquake

We will define a successive occurrence of anomalous fluctuation and earthquake within a short period of time as “successive occurrence of anomalous fluctuation and earthquake.” However, even if there is no relation between the anomalous fluctuation and earthquake, both just happen to occur successively during a short term. Therefore, an unrelated probability $P_{unrel}$ of successive occurrence of both phenomena has to be estimated and to be compared with probability of observational occurrence $P_{obs}$.

In order to derive the formula for $P_{unrel}$, let’s consider that only one anomaly and only one earthquake occurs under no relation during the entire observing period, $T_{all}$. At first, we derive a probability of NOT successive occurrence of both in defined time period $t_{per}$, $P_{unrel}(t_{per})|_{Neq=1}$. To simplify, time of occurrence of anomaly is fixed. The $P_{unrel}(t_{per})|_{Neq=1}$ is
the probability of occurrence of earthquake at complementary time period. Therefore, the $P_{unrel}(t_{per})|_{Neq=1}$ can be obtained as follows.

$$P_{unrel}(t_{per})|_{Neq=1} = \frac{T_{all} - |t_{per}|}{T_{all}}$$  \hspace{1cm} (4)

where $t_{per}$ is the defined length of time period as successive occurrence of anomalous fluctuation and earthquake, $T_{all}$ is the amount of observing time ($T_{all} = 1095$ days). Next, let’s consider two earthquakes occur out of defined time period, $t_{per}$. It’s probability is equal to the square of $P_{unrel}(t_{per})|_{Neq=1}$. Because it is the conditional probability that first earthquake occurs out of $t_{per}$ and second earthquake occurs out of $t_{per}$ too. By the same token, when the number of earthquakes which occur out of $t_{per}$ is $N_{eq}$, the probability can be obtained as next equation.

$$P_{unrel}(t_{per})|_{Neq} = \left( \frac{T_{all} - |t_{per}|}{T_{all}} \right)^{N_{eq}}$$  \hspace{1cm} (5)

where the $N_{eq}$ is the number of occurrence of earthquake during the whole observation period $T_{all}$. The event which the anomaly and earthquakes just happen to occur successively in a defined time period $t_{per}$ is complementary event of $P_{unrel}(t_{per})|_{Neq}$. Therefore, the unrelated probability $P_{unrel}(t_{per})$ of the successive occurrence of the anomaly and earthquakes can be obtained as follows (Motojima and Haga, 2014).

$$P_{unrel}(t_{per}) = 1 - \left( \frac{T_{all} - |t_{per}|}{T_{all}} \right)^{N_{eq}}$$  \hspace{1cm} (6)

The probability of observational occurrence $P_{obs}$ can be obtained from the results of observation, as follows.

$$P_{obs}(t_{per}) = \frac{N_{obs}(t_{per})}{N_{anom}}$$  \hspace{1cm} (7)

where the $N_{obs}(t_{per})$ is the number of successive occurrence of anomalous fluctuation and earthquake in the length of time period $t_{per}$. The $N_{anom}$ is the number of occurrence of anomalous fluctuation during the whole observation period $T_{all}$.

The number of successive occurrence of anomalous fluctuation and earthquakes $N_{obs}(t_{per})$ depends on the length of defined time period $t_{per}$, because the longer defined time period $t_{per}$ makes the more anomalous fluctuation identified as “successive occurrence of anomalous fluctuation and earthquake.” Besides, the unrelated probability $P_{unrel}(t_{per})$ also depends on the $t_{per}$. The longer $t_{per}$ makes the more unrelated probability $P_{unrel}(t_{per})$ too. Therefore, we proposed an original concept of the probability gain $PG$ for estimating the relationship between the anomalous fluctuation and earthquake in the previous paper (Motojima and Haga, 2014). The probability gain $PG$ is the ratio of the observational probability $P_{obs}$ to the unrelated probability $P_{unrel}$, it can be obtained as follows.

$$PG(t_{per}) = \frac{P_{obs}(t_{per})}{P_{unrel}(t_{per})}$$  \hspace{1cm} (8)
If the $PG$ closes to one, comparable probability of both the observational probability $P_{obs}$ and the unrelated probability $P_{unrel}$, it means that there may be no relation between the anomalous fluctuation and earthquake.

5 Result and discussion

The wavelet coefficients vary depending on the scale $a$ of mother wavelet. Moreover, the $N_{eq}$, which is the number of earthquakes during the whole observation period $T_{all}$, also varies depending on the magnitude of earthquakes, depth of hypocenter and epicenter area. Therefore, we searched the best parameters with respect to the probability gain $PG$. Searching parameters are the scale $a$ of Morlet wavelet, the seismic magnitude $M$, depth of hypocenter $D$, distance $L$ between the wave path and epicenter location. Scope of each parameter is listed in Table 2. Target broadcasting wave was NHK FM Tokyo from Sky-tree transmitting station, 82.5MHz. We calculated the probability gain $PG$ in all combinations of parameters, $a$, $M$, $D$ and $L$, combination number was 567. As the result of calculation in all combinations, the largest number of the probability gain $PG$ was $PG = 7.213$ for $a = 9.775$, $M \geq 4.5$, $D \leq 50 km$ and $L \leq 100 km$. It indicates that the occurrence probability of earthquake under appearance of anomalous fluctuation rise up to 7.213 times higher than no anomaly observed.

The probability gain $PG(t_{per})$ also varies depending on the defined length of time period $t_{per}$ as successive occurrence of anomalous fluctuation and earthquake, because both the observational probability $P_{obs}$ and the unrelated probability $P_{unrel}$ change depending on the $t_{per}$. And so, we also calculated the probability gain $PG(t_{per})$ with respect to $t_{per} = -7 \sim +7 (days)$. The sign of $t_{per}$ means successive occurrence of anomaly before or after earthquake. Minus is anomaly prior to earthquake, plus is the opposite. The variation of probability gain $PG(t_{per})$ with respect to $t_{per}$ shows in Fig. 4 for NHK FM Tokyo wave. In Fig. 4 the probability gain $PG(t_{per})$ has a peak at $t_{per} = -1 (days)$. It indicates that anomalous fluctuation appears a day before earthquake frequently. In other minus $t_{per}$ the probability gain $PG(t_{per})$ shows about three or more. On the other hand the $PG(t_{per})$ becomes smaller after the earthquake, it is around one. Figure 4 implies the possibility that anomalous fluctuations occur before earthquakes frequently.

We analyzed other broadcasting waves coming from other stations. The parameters $a$, $M$, $D$ and $L$ are same as the analysis for NHK FM Tokyo in Fig. 4. Table 3 shows the probability gain $PG$ for monitoring waves at our observatory. Incoming waves from Tokyo-tower, Sky-tree, Miyama and Hiranohara stations indicate high probability gain $PG = 3.290 \sim 7.213$. This result implies that the anomalous fluctuations appear on plural waves coming from multidirectional stations. Anomalous fluctuations occur in the incoming VHF waves from line-of-sight region.

In order to discuss the relationship between the anomalous propagation and earthquake, we adopted other benchmarks, which were a hit rate and an alarm rate. The hit rate means a reliability of detection for anomalous fluctuations occurred with earthquakes successively. The alarm rate means a reliability of detection for earthquakes occurred with anomalous fluctuations successively. They can be obtained as following.

$$Hit\ rate = \frac{Number\ of\ anomalous\ fluctuations\ associated\ with\ earthquakes}{Number\ of\ anomalous\ fluctuations}$$ (9)
Both rates are also shown for each wave in Table 3. The result of both rates indicate that our method is short of the level needed to clear the precursor of earthquake. However, high probability gain $PG$ implies the possibility of any existence of the relationship between the anomalous fluctuations and earthquakes.

## 6 Summary

In this paper, the relationship between anomalous line-of-sight propagation and occurrences of earthquake is investigated by monitoring the fluctuations in the received wave. In order to discuss the relationship of both phenomena, we applied the new method which was the wavelet analysis of received wave. Anomalous phenomenon is contained in the shape of anomalous fluctuation of the received wave strength. Using the wavelet analysis, we can find out the anomalous fluctuation in the received wave. Then, we adopted the original evaluation method, which was calculation of the probability gain $PG$. The maximum probability gain $PG$ was 7.213, which appeared in broadcast wave of NHK FM Tokyo, frequency $f = 82.5 MHz$, from Skytree transmitting station. Moreover, other broadcasting waves incoming from line-of-sight region were investigated by using the wavelet analysis and the original estimation. They indicated similar number of $PG$ for NHK FM Tokyo. It means that the anomalous propagation appears in not only specific wave (NHK FM Tokyo) but also multidirectional waves. This result suggests the possible existence of relationship between anomalous fluctuations in radio waves and occurrences of earthquake.

In this paper discussion remains limited to the stochastic method only. Moreover, we can not exhibit any hypothetic model which makes the anomalous propagation associated with earthquake. However, our statistical consequence dose not deny the possible existence of any relationship between the anomalous propagation in radio wave and earthquake. We hope that our results can benefit the research of geophysical electromagnetic phenomena associated with earthquakes.

We investigated only a few wavelet analysis methods. Many analysis methods have not been tried yet. These are in future works.
