Dear Editor:

Thanks very much for your kind decision. We have carefully read through the comments from referee #2 and made proper revisions. In addition, the writing was checked by an English speaking colleague again after edited by “American Journal Experts” and “ELSEVIER Language Editing Services” successively.

Our responses to the referee’s comments and some additional revisions are listed below. We greatly appreciate your time and efforts to improve our manuscript for publication.

Yours sincerely

Bin Zeng

A point-by-point response to the referee #2

The comments from referee #2 below did not appear in the paper review system, but from the email by Editorial Support Anna Wenzel.

The paper on Mechanism of groundwater inrush hazard … is interesting and worth to be printed but not in the present form.

The science in the paper is good and needs no further modification but the language and the style of the manuscript must be changed:

1- English is poor and somewhere it is difficult to understand the meaning of some sentences

Response: We invited an English speaking colleague to check the language of the manuscript and make appropriate revisions. (Before this minor revision, the manuscript was edited by “American Journal Experts” and “ELSEVIER Language Editing Services” successively.)

2- Often along the paper figures 3-4 etc. are wrongly cited (it seems that fig. 2 was added and this presence was not considered in citation along
Response: We checked the whole manuscript to ensure that no figure was wrongly cited anymore.

3- In the reference list the alphabetic order is sometime wrongly followed

Response: We checked the reference list again, and made proper revisions to ensure that all the references listed in right alphabetical order.

The author also made following additional revisions:

- The Fig. 3 was redrawn so as to improve the clarity.
- All the data in the tables were revised to have the same number after the decimal point.
- We also checked the references in the main text to ensure that every reference cited in the text is also present in the reference list (and vice versa).
- We checked our manuscript carefully for typos, co-authors and their affiliations, terminology, updates of data in tables, and updates of variables in equations.
A marked-up manuscript version
Mechanism of groundwater inrush hazard caused by solution mining in a multilayered rock salt mining area: A case study from Tongbai County, China

ABSTRACT

The solution mining of salt mineral resources may contaminate groundwater and lead to water inrush out of the ground due to brine leakage. Taking a serious groundwater inrush hazard in a large salt mining area in Tongbai County, China, as an example, this study mainly aims to analyze the source and channel of the inrushing water. The mining area has three different types of ore beds as follows: 

a) trona (trisodium hydrogendicarbonate dihydrate, also sodium sesquicarbonate dihydrate, with the formula Na₂CO₃•NaHCO₃•2H₂O, is a non-marine evaporite mineral); b) glauber (sodium sulphate, is the inorganic compound with the formula Na₂SO₄ as well as several related hydrates) and c) gypsum (a soft sulphate mineral composed of calcium sulphate dihydrate, with the chemical formula CaSO₄•2H₂O). Based on the understanding of geological and hydrogeological conditions, the study first obtained hydrochemical data of the groundwater at different points and depths, and then analysed the pollution source and pollutant component from single or mixed brines by using both physical-chemical reaction principle analysis and hydrogeochemical simulation method. Finally, possible leakage brine conducting channel to the ground was discussed from both geological and artificial aspects. The results reveal that the brine from the trona mine is the major pollution source; there is a fissure zone in the NW-SE direction controlled by the geological structure that provides the main channels for the leakage brine to flow into the aquifer around the water inrush regions, and a large number of waste gypsum exploration boreholes are the channels that supply the polluted groundwater inrush out of the ground. This research can offer a valuable reference for avoiding and assessing groundwater inrush hazards in similar rock salt mining areas, which is advantageous for both groundwater quality protection and public health.
1. Introduction

Solution mining is commonly used in salt mine exploitation, as salts are soluble in water. In this method, high-pressure and -temperature water with low salinity is injected into a mineral deposit through production wells to dissolve the mineral salts. After being drawn from the wells, the soluble salt is purified and further processed. However, the high-pressure and -temperature water used in this process not only dissolves minerals but can also cause fractures in the strata, which usually results in hazards such as brine leakage or groundwater inrush. In this situation, underground drinking water for the public is normally polluted following groundwater inrush, creating a hazard and threatening the health of local residents.

Many scholars (Clark and Fritz, 1997; Liu et al., 2015; Wu et al., 2016) have studied groundwater inrush hazards in both coal and metal mines, and some adopted methods are as follows: the use of water level–temperature criterion (Yuan and Gui, 2005; Ma and Qian, 2014), stochastic simulation (Fernandez-Galvez et al., 2007), numerical simulation (Liu et al., 2009; Kang et al., 2012; Shao et al., 2013; Houben, et al., 2017), water chemical analysis (isotope analysis, water quality type correlation analysis) (Robins, 2002; Fernandez et al., 2005; Hu et al., 2010; Cobbina et al., 2015; Lee et al., 2016; LeDoux et al., 2016), multivariate statistics (discriminant analysis, clustering analysis) (Chen and Li, 2009; Lu, 2012), fractional advection dispersion equations (Ramadas et al., 2015) and nonlinear analysis (fuzzy mathematics, grey correlation analysis, etc.) (Hao et al., 2010; Gao, 2012). However, due to the particularity of the solution mining method and the complex chemical-physical reactions during the high-pressure and -temperature mining process, researches regarding solution mining was more mainly focused on mining techniques (Jiang and Jiang, 2004; Kotwica, 2008; Namin et al., 2009), mining cavity stability analysis and sinkhole problems (Staudtmeister and Rokahr, 1997; Bonetto et al., 2008; Ezersky et al., 2009; Goldsheider and Bechtel, 2009; Closson and Abou Karaki, 2009;
Vigna et al., 2010; Frumkin et al., 2011; Ezersky and Frumkin, 2013; Qiu, 2011; Blachowski et al., 2014), and geohazards particularly in karst areas due to human-induced underground caving (Waltham and Fookes 2003; Parise and Gunn 2007; Zhou and Beck 2011; Parise and Lollino 2011; Lollino et al., 2013; Gutierrez et al., 2014; Parise et al., 2015), but rarely on source and channel analysis of inrush water in a solution mining accident.

The studied study case of rock salt mining area is located in Tongbai County, Henan Province, China. This mining area has the second largest trona reserves in the world, while its glauber salt reserves reach 45 million tons. Since trona and glauber salt were put into production in 1990 with single- and double-well convection mining as the main producing method, five inrush points appeared in the town of Anpeng, Tongbai County, from June 2011 to May 2013. Among these five inrush points, four (Y1~Y4) were long-term (longer than 2 years) inrush points with stable discharge, while one (Y-5) was a sudden inrush point (as shown in Fig. 1 and Fig. 2). On 1 February 2013, almost 200 m³ of mud and sediment erupted out of the ground at the Y-5 point on 1 February 2013. The area of the inrush point was almost ~4 m²; the average water inflow was from 20-30 m³/d while the greatest inflow reached 200 m³/d. The water inrush lasted for approximately three months. During the Y-5 inrush accident, according to the field investigation, a trona production well named “S02,” which is 200 m far from the inrush point, broke at a depth of 234 m and remained broken for a long period of time. It was repaired on 15 March 2013. During the entire water inrush process, the groundwater inrush–of groundwater led to a phenomenon of salinization at the house base of the houses of many villagers, and made water in many residents’ wells no longer drinkable.

Since the groundwater inrush hazard involved a wide geographic area and the inrush source was quite hard to distinguish due to the multi-layer distribution of the different ore bodies and the complexity of the inrush water component. Therefore, in order to put forward a targeted treatment
program to stop the water inrush as soon as possible, and mitigate the groundwater pollution in
research region, the source and channel of the inrush water were taken as the research emphasis in this
study. Furthermore, this research can provide a valuable reference for avoiding and assessing
groundwater inrush hazards in similar rock salt mining areas, which is advantageous for both
groundwater quality protection and public health.

2. Geological and hydrogeological setting

2.1. Geological conditions

The mining area is located in northwestern Tongbai County. The landscape is characterized by hollows and ridges, and has an elevation ranging from 140 to 200 m above sea level. The strata, lithology, aquifer, and the position of different ore beds in the research area (Shi et al., 2013) are shown in Fig. 3.

According to geologic references and field investigation, in the northeastern mining area, a hidden east-west oriented fault is developed at the bottom of the first segment of the Hetaoyuan Formation, and another four, hidden, south-north oriented faults are developed at the bottom of the second segment of the Hetaoyuan Formation. These five faults are outside the scope of trona mine, so they have little effects on the ore bed. A few small-scale hidden faults are developed at the bottom of the third segment of the Hetaoyuan Formation, although within the scope of the glauber salt mine, they have little effects on the glauber salt ore bed which is distributed at the top of the first segment of Hetaoyuan Formation. A hidden east-west oriented fault is developed at the bottom of the Liaozhuang Formation in the range of the glauber salt mine, but it has little effects on the glauber salt mine because of its small scale.

2.2. Hydrogeological conditions

The groundwater in the mining area can be divided into pore water in the loose rock mass and
bedrock fissure water according to the lithology and hydrogeological features. In the upper part of the Liaozhuang Formation, a mudstone interbedded with gypsum is considered a relative weak permeable stratum especially under the condition of high-pressure and -temperature water injection during the mining period. The shallow aquifer is unconsolidated pore water above this weak permeable stratum, while the deep aquifer is a bedrock fissure beneath this weak permeable stratum.

The flow direction of the shallow groundwater is controlled by the overall regional terrain. Taking the underground watershed as the boundary, the groundwater on the south side of the watershed is mainly flowing from northeast to southwest with the Yanhong River as the drainage base of the drainage, while the groundwater on the north side of the watershed is mainly slow-flowing from south to north with the Xia River as the drainage base of the drainage. The deep groundwater has is in relatively closed burial conditions, with slow velocity, and nearly the same flowing direction as the shallow groundwater.

The water inflow of a single well with poor water content is approximately 100 m³/d, while it can reach from 1000-2000 m³/d if it has rich water content. The annual amplitude variation of the groundwater level is from 2- to 4 m, while the depth is stable at 2.3-4 m. Residents in Anpeng use groundwater as the source of their drinking water, which comes from wells and is from the porous aquifer.

As shown in Fig. 3, Gypsum mainly occurs on the top of the Liaozhuang Formation, glauber salt occurs in the third member of the Hetaoyuan Formation, and the trona occurs at the bottom of the second member of the Hetaoyuan Formation as well as on top of the first member of the Hetaoyuan Formation (Fig. 3). The surrounding rocks of every mineral layer, including mudstone, shale, sandy conglomerate, psammitic rock and dolomite, which have sufficient thickness and good water-resistance. Therefore, the effect of groundwater on the mineral deposit is minimal in the mining area.
2.3 Distribution and characteristics of the ore body

The three ore bodies overlap in plane distribution, as shown in Fig. 4. The vertical distribution of the ore bodies from deep-to-shallow is trona (buried depth: 1560.92-2929.53 m), glauber salt (buried depth: 1003.66-1397.58 m) and gypsum (buried depth: 134-338 m). The trona and glauber salt bodies are at least 250 m apart from each other vertically.

The trona has 11 horizontal layers, with an average thickness of 2.11 m. The chemical composition of trona is mainly NaHCO$_3$ (average of 77.06%) and Na$_2$CO$_3$ (average of 16.33%) (Wang, 1987). The glauber salt has 4 layers, with an average thickness of 8.93 m. The dip angle of the ore bed layer is less than 10°. The average mineral grade is 60.14%. The main composition of the glauber salt is Na$_2$SO$_4$ (>90%) with a small amount of NaCl.

3. Methods

Based on the field investigation results, the chemical characteristic analysis of the inrush water at different sites and time, analysis of the physical and chemical reaction principles for the different brines, and combined with the PHREEQC simulation method, the source of the inrush water was determined.

3.1. Sampling and testing

The five groundwater inrush points (Y1~Y5) and some shallow groundwater points (resident wells: SY1~SY6) near the accident site were chosen as groundwater quality sampling points, as shown in Fig. 4. Water from each point was sampled on 9 March 2013.

Water samples were filtered using a 0.45 μm millipore filtration membrane in the field, and then filled with a polyethylene bottle which had been soaked in acid and washed with deionised water. Filtered water samples were acidified until the pH<2 by addition of ultra-pure HNO$_3$ for the determination of cations; water samples for the determination of anions were not treated.

Elements tested in the laboratory included 26 cations (K$^+$, Na$^+$, Ca$^{2+}$, Mg$^{2+}$, Sr$^{2+}$, etc.) and 5 anions...
(F, Cl, NO₃, SO₄²⁻, NO₂⁻). The instrument used for the determination of cations was an inductively
coupled plasma atomic emission spectrometer (Agilent ICP-OES 5100), and the minimum detection
limit was 0.0001 mg/L. The instrument used for the determination of anions was an ion chromatograph
(ICS-1100), and the minimum detection limit was 0.001 mg/L. CO₃²⁻ and HCO₃⁻ were tested according
to the “Groundwater quality test method: Determination of carbonate and bicarbonate by hydroxide
titration (DZ/T 0064.49-93),” and the minimum detection limit was 0.01 mg/L.

In addition, from March to April 2013, at the Y-5 and Y-3 points, three water quality automatic
recorders (Levelogger gold, Canada) were arranged for inrush water monitoring. Monitoring indicators
were temperature, water level and electrical conductivity. The purpose of the monitoring was to fully
understand the inrush water quality during the whole accident, especially in the process of well
reparation.

3.2. Analysis of the physical and chemical reaction principles in different brine mixing conditions

During the accident, the leakage brine of the trona (2000 m belowground) or glauber salt (1000 m
belowground) might flow through the gypsum deposit (200-400 m belowground), which is comprised
primarily of CaSO₄, and cause physical and chemical reactions while it inrushes out of the ground. Thus,
the formation of the inrush water chemistry component might be from glauber brine, or
trona brine, or a mixture of the two brines, flowing through the gypsum layer with accompanying
physical and chemical reactions. To provide the basis for further analysis of the inrush water source, the
physical solubility of the gypsum and the reaction when the glauber salt brine, trona brine, or a mixture
of trona and glauber salt brine flowing through the gypsum deposits were analyzed.

3.2.1. The physical solubility of gypsum (CaSO₄)

Gypsum is slightly soluble; when in water, its acidity is apparent. Eq. (1) provides the dissolution
rate equation of gypsum in water:
\[ R_{\text{Gypsum}} = k_1 \times \frac{A_g}{V} \left( 1 - \frac{IAP}{K_{\text{Gypsum}}} \right) \]  \hspace{1cm} (1)

- \( R_{\text{Gypsum}} \): the dissolution rate of gypsum; \( k_1 \): rate constant; \( A_g \): the surface area of gypsum; \( V \): the liquid volume in contact with the gypsum surface; \( IAP \): the product of ion activity; and \( K \): ion solubility product.

- \( \frac{IAP}{K_{\text{Gypsum}}} \) is affected by the temperature; thus, it is the same as \( R_{\text{Gypsum}} \).

The solubility of gypsum in water reaches a maximum of 0.2097 g/100 g at 40°C. The solubility decreases when the temperature is below or above 40°C. The content of SO\(_4^{2-}\) and Ca\(^{2+}\) obtained by physical dissolution is very low.

### 3.2.2. Gypsum (\( \text{CaSO}_4 \)) dissolved by glauber salt brine (\( \text{Na}_2\text{SO}_4 \))

Equations (2) and (3) show the reactions of Na\(_2\)SO\(_4\) and CaSO\(_4\) with water.

\[ \text{Na}_2\text{SO}_4 \rightleftharpoons 2\text{Na}^+ + \text{SO}_4^{2-} \quad \hspace{1cm} (2) \]

\[ \text{CaSO}_4 \rightleftharpoons \text{Ca}^{2+} + \text{SO}_4^{2-} \quad \hspace{1cm} (3) \]

Because of the common-ion effect, the solubility of the electrolyte will decrease when a strong electrolyte with the same ion is placed into an electrolyte-saturated solution. Thus, the solubility of gypsum will be reduced when glauber salt brine flows through and dissolves the gypsum deposits; the gypsum will be even harder to dissolve in this situation. Thus, if the glauber salt brine flows through the gypsum deposits, the brine characteristic would not apparently change.

### 3.2.3. The reaction of trona brine or a mixture of trona and glauber salt brine with gypsum

The HCO\(_3^-\) and CO\(_3^{2-}\) contents in trona brine or in mixed brine are very high as is the solution alkalinity and pH. If the reaction kinetics is not taken into account, the pH has little influence on the dissolution of gypsum (Yang, 2003; Xu and Li, 2011). The reaction occurs when the brine with high concentrations of HCO\(_3^-\) and CO\(_3^{2-}\) flows through the gypsum deposits. The main chemical reactions are
as follows:

\[
\text{Na}_2\text{CO}_3 + \text{CaSO}_4 \rightleftharpoons \text{Na}_2\text{SO}_4 + \text{CaCO}_3 \downarrow \quad (4)
\]

\[
2\text{NaHCO}_3 + \text{CaSO}_4 \rightleftharpoons \text{Ca(OH)}_2 + \text{Na}_2\text{SO}_4 + 2\text{CO}_2 \uparrow \quad (5)
\]

In Eq. (4), \(\text{CaSO}_4\) is slightly soluble, while \(\text{CaCO}_3\) is insoluble. The reaction easily occurs when an insoluble substance is produced by a slight soluble substance, and the ionic equation is as follows:

\[
\text{CO}_3^{2-} + \text{CaSO}_4 \cdot 2\text{H}_2\text{O} \rightleftharpoons \text{SO}_4^{2-} + \text{CaCO}_3 \downarrow + 2\text{H}_2\text{O} \quad (6)
\]

The Gibbs Free Energy \(\Delta G\) is -22.7 kJ/mol under the standard state. When \(\Delta G\) is negative, the reaction, which is endothermic, occurs freely. The reaction is faster at higher temperatures. Eq. (5) shows that \(\Delta G\) is 2102 kJ/mol under the standard state. When \(\Delta G\) is positive, the reaction will not freely occur.

Thus, the reaction shown in Eq. (5) will not occur, but the chemical reaction will still proceed as shown in Eq. (4), when trona brine or mixed brine flow through the gypsum deposits.

### 3.2.4. The carbonate equilibrium effect during the reaction of different brines

The carbonate equilibrium that exists in the trona brine or mixed brine is affected by pH. The carbonate in groundwater exists in three forms: free carbonic acid, bicarbonate and carbonic acid.

In the trona brine (pH>10), the concentration of \(\text{HCO}_3^-\) is 5-20 times that of the concentration of \(\text{CO}_3^{2-}\), and \(\text{CO}_3^{2-}\) in the brine is dominant in this case. When the trona brine flows through the gypsum, \(\text{CaSO}_4\) reacts with \(\text{CO}_3^{2-}\) and \(\text{CaCO}_3\) precipitates. If the concentration of \(\text{CO}_3^{2-}\) in the brine decreases, a reversible reaction will take place and drive the equilibrium to the right. Thus, the reverse reaction will occur when the trona brine flows through the gypsum as follows:

\[
\text{CO}_3^{2-} + \text{CaSO}_4 \rightleftharpoons \text{SO}_4^{2-} + \text{CaCO}_3 \downarrow \quad (7)
\]

\[
\text{HCO}_3^- \rightleftharpoons \text{H}^+ + \text{CO}_3^{2-} \quad (8)
\]

The circular reactions as shown in Eqs. (7) and (8) will occur when mixed brine flows through the
gypsum because it has similar properties to the trona brine. Thus, taking the carbonate equilibrium effect into account, the concentrations of HCO$_3^-$ and CO$_3^{2-}$ will decrease, while SO$_4^{2-}$ increases after CaCO$_3$ precipitates.

3.3. Simulation of groundwater inrush source

For further quantitative analysis of the inrush water source and component, the international hydrological and geochemical simulation software PHREEQC was used to simulate the water-rock interaction. The PHREEQC software was developed by the U.S. Geological Survey, and it is able to calculate geochemical action within a temperature range of from 0~300 degrees (Wei, 2010).

Based on the deduction that the main water inrush source around Anpeng was trona leakage brine, the simulation method PHREEQC was used and combined with the possible channel of inrush water to establish a conceptual model and then hydrogeochemical simulation of the water-rock interaction was conducted. Subsequently, the mixed ratio of inrush groundwater and shallow groundwater around Anpeng were quantified, which can better verify the source of the inrush water.

3.3.1. Conceptual model

Around Anpeng, the trona leakage brine flowed through the specified mineral assemblages and mixed with shallow groundwater in different proportions.

3.3.2. Initial data input

The parameters of the trona brine were taken from the enterprise’s production testing data; the parameters of the shallow groundwater were taken from the same aquifer but outside the study area, and can basically represent groundwater background values. The specific parameters are shown in Table 1.

3.3.3. Setting of stratum and mineral

The formations from the bottom to the top during the process of the leakage brine flowing into the shallow groundwater and then flowing out of the ground were as follows: the third member of the
Hetaoyuan Formation of Paleogene, and the Liaozhuang Formation and the Fenghuang Formation of Neogene and Quaternary, respectively. To simplify the mining area, according to the thickness of the rock stratum and the proportion of mineral composition, it can be assumed that the layer through which the trona brine flowed contains Ca-montmorillonite, kaolinite, gypsum, potash feldspar and potash mica.

The main ingredients are as follows: Kaolinite: $\text{Al}_4[\text{Si}_4\text{O}_{10}](\text{OH})_8$; Gypsum: $\text{CaSO}_4\cdot2\text{H}_2\text{O}$; Ca-montmorillonite: $(\text{Na},\text{Ca})_{0.33}(\text{Al},\text{Mg})_2[\text{Si}_4\text{O}_{10}](\text{OH})_2\cdot\text{nH}_2\text{O}$; Dolomite: $\text{CaMg(CO}_3)_2$; Potash feldspar: $\text{K}[\text{AlSi}_3\text{O}_8]$; Potash mica: aluminium silicate as K, Al, Mg, Fe and Li.

4. Results and Discussion

On 9 March 2013, in Anpeng, water samples from five groundwater inrush points and six surrounding water quality monitoring points (resident well) were tested. The results of water chemical composition are shown in Table 2, and the distribution of the sampling points is shown in Fig. 4.

According to the water quality analysis, the inrush brine had a relatively high salinity, with some inrush water samples containing $\text{SO}_4$-Na and some containing $\text{HCO}_3$-Na. The crystals mainly consisted of $\text{NaSO}_4$, $\text{Na}_2\text{CO}_3$, and $\text{NaHCO}_3$. The composition of the inrush water and the crystals was the same as that of the high-concentrated ions in the trona brine ($\text{Na}_2\text{CO}_3$, $\text{NaHCO}_3$, etc.) and glauber salt brine ($\text{Na}_2\text{SO}_4$).

4.1. The source of the inrush water

An automatic water quality recorder was set up at the Y5 inrush point on 4 March 2013. The monitoring lasted from 5 March to 20 March 2013. Thus, the relationship between the inrush points and the S02 well can be assessed according to the correlation of the changes between temperature/electrical conductivity and the concentration of brine during the S02 production well reparation period (5 March to 14 March 2013).
The production of glauber ceased during the investigation (2 March to 15 March 2013), so it could be determined how the glauber mining affects the water inrush hazard based on a dynamic water quality situation.

4.1.1. The source of inrush water at the Y-5 point

After successful reparation of the S02 well, the conductivity and temperature of the inrush water decreased significantly. The $\text{CO}_3^{2-}$ concentration remained at 0, the $\text{HCO}_3^-$ concentration decreased to 500 meq/L, while the $\text{SO}_4^{2-}$ concentration increased to 600 meq/L. Subsequently, the concentrations of these three ions were in a state of dynamic balance. The analysis shows that the source of the inrush water at the Y-5 point is closely related to the S02 trona well.

In order to ensure whether the glauber brine exists at this point as part of an inrush source, further analysis was performed. The depth of the well rupture was 234 m; the gypsum deposit was developed to this depth. While the leakage of the trona brine flowed through the gypsum deposit, reactions would occur as shown in Eqs. (7) and (8).

According to the ion milliequivalent concentrations ($\text{Ca}^{2+}$: 0.61 meq/L; $\text{CO}_3^{2-}$: 905.3 meq/L; $\text{HCO}_3^-$: 1332.94 meq/L; $\text{Cl}^-$: 107.43 meq/L; and $\text{SO}_4^{2-}$: 267.89 meq/L) at the Y-5 point, the concentration of $\text{Ca}^{2+}$ was negligible compared to the other main ions. Only the reaction between $\text{CO}_3^{2-}$ and $\text{CaSO}_4$ had to be taken into account because of the large number of $\text{CO}_3^{2-}$, with fast velocity, the short contact time with gypsum, and the high temperature. The reaction of $\text{CO}_3^{2-}$ and $\text{CaSO}_4$ would take place at a ratio of 1:1 according to Eq. (7), and three types of inrush water sources could be assumed under this precondition as follows:

1. The inrush water source was only from the trona brine.

The $\text{CO}_3^{2-}$ and $\text{CaSO}_4$ in the brine reacted at a ratio of 1:1, and the concentration of $\text{SO}_4^{2-}$...
concentration was equal to the reacted $\gamma \text{CO}_3^{2-}$ content. Thus, the $\gamma \text{CO}_3^{2-}/\gamma \text{HCO}_3^-$ ratio in the trona brine was equal to the $\gamma (\text{CO}_3^{2-}+\text{SO}_4^{2-})/\gamma \text{HCO}_3^-$ ratio in the inrush water. From this calculation, it could be seen that $\gamma (\text{CO}_3^{2-}+\text{SO}_4^{2-})/\gamma \text{HCO}_3^-$ was equal to 0.88, while $\gamma \text{CO}_3^{2-}/\gamma \text{HCO}_3^-$ ranged between 0.86 and 1.26. The content of $\gamma (\text{CO}_3^{2-}+\text{SO}_4^{2-})/\gamma \text{HCO}_3^-$ was similar to $\gamma \text{CO}_3^{2-}/\gamma \text{HCO}_3^-$; therefore, the source of the inrush water was exclusively trona brine.

(2) The inrush water source was only from the glauber brine.

The $\gamma \text{SO}_4^{2-}/\gamma \text{HCO}_3^-$ ratio in the glauber brine was equal to 1237.8, compared to 0.19 in the inrush water. Therefore, this assumption was incorrect because of the widely varying ratios.

(3) The inrush water source was from a mixed brine of glauber and trona.

Assuming that the contribution ratio of the glauber brine was $X$ and that of the trona brine was $Y$ was true, then $1237.8 \times X + (0.86 \sim 1.26) \times Y = 0.88$. This equation showed that when the contribution ratio of the trona brine was equal to 1, the contribution ratio of the glauber brine was equal to $1.6 \times 10^{-5}$, and which is too small to be ignored.

Thus, it could be confirmed that the water inrush source at Y-5 was exclusively the leakage of trona brine from the broken S02 well.

4.1.2. The sources of inrush water at the Y-4, Y-3, Y-2, and Y-1 points

The inrush water quantity and the dynamic variation of the concentration of $\text{SO}_4^{2-}$ and $\text{HCO}_3^-$ at points Y1-Y4 were not obvious when the S02 well was under repair and all the glauber wells were shut down (2-15 from 2 to 15 March). This result shows that the sources of these water inrush points were not due to the underground mining activities of the glauber brine or the rupture of the S02 well, but because of the brine leakage from other trona wells.

4.1.3. Components and mixed proportions of the inrush water

The PHREEQC simulation conditions were assumed to be as follows: (1) the trona brine did not
mix with shallow groundwater after flowing through the mineral layer; or (2) the trona brine mixed with shallow groundwater in a ratio of 1:2, 1:10, 1:100, 1:200, 1:500, 1:1000 and 1:5000 after flowing through the mineral layer. The simulation results are shown in Table 3.

Table 3 shows that when the trona brine flowed through the stratum and shallow groundwater, the concentrations of Na$^+$, Cl$^-$ and SO$_4^{2-}$ decreased while the concentration of HCO$_3^-$ increased with increasing proportion of the shallow groundwater. The concentration of Ca$^{2+}$ decreased at first and then increased.

The ion concentrations at Y-5, except for SO$_4^{2-}$, were similar to the ion concentrations in the trona brine. However, at the same time, the concentration of HCO$_3^-$ was nearly 0 meq/L. When the trona brine flowed through the layer, it would react rapidly and pour out of the ground directly because of the fast velocity of the inrush water at Y-5. Meanwhile, the trona brine was not continuously provided in the simulation. Thus, the concentration of HCO$_3^-$ would be near to the concentration of trona brine in reality. Therefore, the trona brine must have a rapid inrush, nearly not mixing with shallow groundwater.

The PHREEQC simulation analysis results show that: 1) the water inrush source of Y-5 was nearly all of the trona brine from the ruptured S02 well; 2) the water inrush source of Y-3 was a mixture of trona brine and groundwater in a ratio of from 1:10~1:100; and 3) the water inrush sources of Y-4, Y-2 and Y-1 were a mixture of trona brine and groundwater under the ratio of 1:200.

4.2. The channel of the inrush water

4.2.1. Reasons for the brine leakage

Trona is produced by either a single well or double/multiple well convection mining method, a that is water-soluble mining method (Lin, 1987). The main mining unit consists of a salt cavity and production well. Thus, the instability of the salt cavity and the rupture of the production well are the
main possible reasons for brine leakage.

1) Analysis of salt cavity stability

The possibility of salt cavity collapse: Trona is distributed at the bottom of the second member of the Hetaoyuan Formation and in the upper part of the first member of the Hetaoyuan Formation, with dolomite strata developed in the roof and floor. The thick and hard surrounding rock structure determined that the cavity is produced by hydrofracture but it is hard to fill with large-scale fractured channels and can remain intact and stable.

The development of a roof fracture: When a mineral is under exploitation, the surrounding rock in the cavity is under pressure from the inner brine. This pressure is equal to the sum of the water injection pressure and the water column pressure in the production well. The water injection pressure of the trona production well is approximately 10-20 MPa, while the 1560.92-2929.53 m (mineral buried depth) water column pressure is approximately 15.3-28.71 MPa. Thus, the greatest water pressure on the surrounding rock in the cavity is 48.71 MPa. The main lithology of the surrounding rock is dolomite which is 500 m in thickness and 142.66 MPa in compressive strength, which is nearly 3 times that of the greatest possible water pressure. Therefore, large-scale fractures in the surrounding rock of the trona mineral would be difficult to develop under the effect of sustained water pressure.

2) Analysis of production well rupture

The phenomenon of brine leakage caused by the S02 well rupture in Anpeng indicates that production well damage is an important cause of brine leakage. The depth of the S02 well rupture is 234 m underground, i.e. in the gypsum deposit, which is strongly hygroscopic. The pressure caused by the water swelling is approximately 0.15 MPa (Li and Zhou, 1996), which may damage the production well and induce brine leakage. The high concentration of SO₄²⁻ (>250 mg/L) generated by the reaction of leakage brine and gypsum can also corrode the production well and lead to groundwater inrush.
4.2.2. Analysis of water-conducting channel

According to our analysis, the most probable reason for brine leakage in trona is production well rupture. The leaking brine will flow along the water-conducting channel into the shallow aquifer and even pour out of the ground. However, the geological structure in the mining area shows no water-conducting fault development. Thus, the water-conducting channel, that the leakage brine flows along, is probably a fissure or artificial channel.

A structural fissure is the main type of fissure that occurs in groundwater inrush hazards when using the solution mining method. The structural fissure is determined by the maximum horizontal principal stress, which is controlled by the tectonic stress field in the mining area. The connection direction of the S02 well and the other water inrush points is NW-SE, which is the same as that of the structural fissure zone development direction. This indicates that the main water-conducting channel in Anpeng is controlled by the structural fissure zone.

The inrush points in Anpeng are all at the abandoned gypsum exploitation wells, which were not closed properly. Thus, high-pressure cavity water or leakage brine can flow along the structural fissure zone, finally connect with these wells, and then pour out of the ground through boreholes. Therefore, the abandoned gypsum exploitation wells are the main channels through which the shallow polluted groundwater flowed out of the ground, as shown in Fig. 5.

5. Conclusions

This study aimed to investigate the source and channel of the inrush water in a multilayer rock salt mining area. To achieve the set objectives, this study combined an analysis of geological and hydrogeological conditions, an analysis of physical and chemical reaction principles of different brines, the PHREEQC simulation method, and an analysis of geological and artificial reasons for the conducting channel where leakage brine flowed from the damage depth out to the ground.
combined as the study methodology.

Long-term solution mining with high-pressure and -temperature water not only dissolves minerals but also may cause rupture of strata and damage of the production well, which usually results in brine leakage or the inrush of groundwater inrush. Geological and hydrogeological conditions are the basis which determines the total risk of the groundwater inrush hazard. Physical and chemical reaction principle analysis of different brines and hydrogeochemical simulation of water-rock interaction in different assumed conditions using the PHREEQC simulation method can not only determine the exact source of the leakage brine but also identify the mixed proportion of inrush water while the leakage brine flows through the mineral layer in different way. Other than geological reasons, mining techniques such as pressure control of injection water and groundwater quality monitoring of exploitation wells may also determine the risk of a groundwater inrush hazard in a multilayer rock salt mining area.
