Abstract. Coastal local communities and assets are exposed to flooding and erosion hazards due to impacting extreme storm events that are likely to increase in intensity in the medium- and long-term. Coastal managers are requested to provide risk management plans supported by actions taken at the different phases of the disaster cycle aiming at better understanding and coping with risk. Effective and rapid post-event beach surveys are therefore necessary to collect physical data in the immediate aftermath of an event. Additionally, the inclusion of local stakeholders in the assessment process is essential to properly understand the social dimension of the problem. In this study, a local protocol for post-event assessment, the Quick Response Protocol, was tested on a pilot site on the Emilia-Romagna (Italy) coast in the aftermath of an extreme event occurred in February 2015. Physical data were collected using both Real-Time Kinematic Geographical Positions Systems and Unmanned Aerial Vehicle platforms. Local stakeholders were interviewed collecting qualitative information on the situation before, during and after the event. Results were analysed and compared with the outcomes of regional reports on the impacts of the event showing a higher level of detail and reliability. The local approach, although improvable from different technical aspects, can be easily integrated in the regional ones improving the resolution and completeness of the regional-scale assessments.

1 Introduction

Extreme storm events have the potential to create coastal flooding and erosion, reshape coastlines, impact infrastructures, and expose populations to hazardous conditions. The most damaging events consist of a combination of extreme wave heights, storm surge, wind direction, and tidal stage that interact with the morphology of the beach and adjacent infrastructures generating direct and indirect impacts (Van Dongeren et al., 2017; Viavattene et al., 2017). Given the expectation of increasing storm intensities and occurrence (Bason et al., 2007), accurate and rapid field data collection must occur to best inform risk management and policy decisions (Casella et al., 2016). To ensure that appropriate (risk) management plans are implemented, precise and high-resolution field measurements are crucial to understand storm effects on exposed communities and to provide input for numerical modelling for future impact prediction purposes (Lee et al., 1998; Stone et al., 2004; Nicholls et al., 2007).
Additionally, the inclusion of local stakeholders in the assessment process is essential to appropriately address group values, create risk reduction plans supported by locals, and implement the plan with the public (Martinez et al., 2017). Coastal managers are requested to adopt plans and protocols for risk management, ranging from prevention, preparedness, response and recovery phases of the risk cycle. The importance of standardized protocols for risk management is recognized across Europe as an effective way to coordinate field efforts, improve hazard maps, and enhance risk reduction plans (Poljanšek et al., 2017).

Post-storm assessments require capturing the morphologic signature of the event using rapid, quantitative mapping as soon as safe conditions allow following the event but before recovery processes begin (i.e. natural or human-driven) (Morton et al., 1993; Bush et al., 1999; Morton, 2002). To properly quantify impacts, pre-storm quantitative mapping of the area is necessary before impacts can be attributed to a single storm. In recent years, autonomous platform methodologies for coastal mapping and extreme event impact assessment were proposed and tested to improve traditional, expensive, or time-consuming mapping approaches on both the emergent beach (Mancini et al., 2013; Casella et al., 2016; Turner et al., 2016) and the submerged nearshore area (Trembanis et al., 2013).

Real-Time Kinematic Geographical Positions Systems (RTK GPS) for ground-based surveys (Morton et al., 1993; Theuerkauf and Rodriguez, 2012) is the traditional method for data collection requiring highly accurate (sub-decimeter) positioning measurements and is utilized in the coastal environment for temporal and spatial monitoring of many coastal morphologic features (Larson and Kraus, 1994; Benedet et al., 2007; Hansen and Barnard, 2010; Theuerkauf and Rodriguez 2012). Since the accuracy of beach morphology representation is affected by the sampling point density of the RTK GPS survey, insufficient resolutions (e.g. representing the beach with traditional profile spacings of more than 100 meters) can lead to imprecise or misleading morphological interpretations (Swales, 2002; Berstein et al., 2003; Pietro, et al., 2008; Theuerkauf and Rodriguez, 2012). The ideal resolution of the RTK GPS survey depends on the scale of the study and on its location. Terrestrial laser scanners or total stations improve point density but require similar time and physical effort as RTK GPS, particularly when surveying large areas (Saye et al., 2005; Theuerkauf and Rodriguez, 2012; Lee et al., 2013). Improvements in remote sensing technology have increased data resolution through airborne lasers (LiDAR) and satellite imagery but the high costs of operations and infrequent surveys render these options impractical for local scales and rapid or frequent repeated surveys (Stockdon et al., 2002; Young and Ashford, 2006; Anderson and Gaston, 2013). A recent LiDAR application was proposed by Phillips et al. (2017) by fixing a laser system on a building to continuously monitor beach profiles. The system provided interesting results for beach recovery analysis and showed great potential for future applications. However, the measurements are performed on a single location, in the cross-shore direction, thus limiting the scope of data and ignoring the varied, three-dimensionality of coastal response.

Attempts to alleviate these sampling issues stem from recent improvements in autonomous technology such as Unmanned Aerial Vehicles (UAVs or drones), which accommodates local scales, rapid and frequent surveys, and economic feasibility coupled with accurate results for monitoring hydro-morphological changes in the coastal zone (Berni et al., 2009; Westoby et al., 2012; Casella et al., 2016; James et al., 2017). Moloney et al. (2017) compared surveying methods for coastal dune
monitoring in New Zealand. Compared to total station RTK GPS and terrestrial laser scanner methods, the low-cost UAV system resulted the most efficient one, reaching also more accuracy on processed data if compared to total station RTK GPS method. The UAVs resulted ideal to monitor short- and long-term coastal dune systems with elevation data and aerial images. Similarly, Seymour et al. (2017), compared terrestrial laser scanner and UAV, equipped with a RTK GPS system, for coastal monitoring and management in North Carolina (US). This study provided additional insights for field implementation and post-processing, including limitations of UAV data related to the environment (e.g. texture of the surveyed surface, solar angle, etc.). Specific guidelines about these systems were also given and the study claimed that UAVs provide an affordable way to frequently monitor coastal environments at the local scale for coastal management purposes.

Focusing on the social dimension of the problem, it was demonstrated that the inclusion of local people in the processes of coastal risk assessment and preparation of reduction plans, improves the quality of the analysis and has a positive feedback on the population, through increased risk awareness and preparedness (Pescaroli and Magni, 2015; Becu et al., 2017; Gray et al., 2017; Martinez et al., 2017). In this sense, performing interviews of local people in the immediate aftermath of a coastal extreme event can provide important information on the local evolution of the storm as well as on the effectiveness of the implemented emergency preparedness and response phases (Martinez et al., 2017).

Here, a pilot case study application of a quick response approach for local post-storm assessment, utilizing a combination of traditional on-the-ground RTK GPS surveys together with aerial imagery gathered by an UAV for digital photogrammetric reconstruction further supported by qualitative data collection (i.e. interviews of local stakeholders), is presented. This combination of technologies allows for a rapid and holistic coverage of the field site and storm event. The testing was carried out in the Emilia-Romagna region, which managers already adopted effective protocols for coastal risk management and, of interest for this work, regarding early warning system and post-storm hazard and risk assessments (Ligorio et al., 2012; Perini et al., 2015b, 2016). The presented results demonstrate the proposed approach can provide local-scale high-resolution data capturing coastal storm effects. Furthermore, this integrated approach provides detailed insights into the physical and social aspects that can be applied at the local, as well as at regional and national levels, for effective, coordinated cross-disciplinary management purposes.

2 Case study

2.1 Regional settings and study site

Regional Settings

A stretch of approximately 7 km coastal area in the Ferrara province (Emilia-Romagna region), located on the Italian side of the Northern Adriatic Sea (Figure 1A, B), was surveyed right after an extreme (low-frequency and high-impact) storm event (hereafter called the Saint Agatha storm, see Section 2.3) that occurred on 5-7 February 2015. The coastal landscape in Emilia-
Romagna is generally comprised of low-lying sandy beaches with limited topographically elevated areas usually in the form of either relict beach ridges or artificial embankments (Armaroli et al., 2012). The shore is comprised of alternating spaces of natural areas with native dunes intermixed with more prevalent urbanized areas. Most of the shore is now occupied by tourist facilities, residential buildings, and bathing structures often replacing the ancient coastal dune ridges (Sytnik and Stecchi, 2014), as consequence of 60 years of continuous development and urbanization. The touristic beaches are characterized by the presence of private concessions (i.e. properties located on public beach areas, granted to privates for commercial/tourism activities) that provide sun-and-bath and food services since 1970s. Immediately behind the concessions, small residential towns developed and nowadays accommodate many second houses, accommodation and restoration services. These factors combine to increase the area’s exposure to coastal hazards (i.e. flooding and erosion), especially in the Ferrara and Ravenna provinces, where some elevations are below Mean Sea Level (MSL) (Perini et al., 2010), and several defence structures (groins, breakwaters, etc.) have been built along the coast in an effort to mitigate shoreline retreat (Armaroli et al., 2012). Since the end of World War II, in fact, a sediment deficit has affected the littoral budget due to decreased sediment transport towards the shore by local rivers, mainly caused by anthropogenic controls on the rivers and their basins (Preciso et al., 2012) and the reforestation of the Apennines (Billi and Rinaldi, 1997). This problem has been exacerbated over the last several decades by land subsidence, most likely caused by groundwater and gas extraction activities (Teatini et al., 2005; Taramelli et al., 2015).

The wave climate for the region is characterized by low wave energy (mean $H_s \approx 0.4$ m, $T_p \approx 4$ s) with a semidiurnal microtidal regime (neap tidal range = 0.30 m; spring tidal range = 0.8 m). Storm significant wave height with 1-year return period range up to 3.3 m (Armaroli et al., 2009) and storm surges with a 2-year return period are up to 0.6 m (Masina and Ciavola, 2011). These storm events mainly occur in the fall and winter months (October-March). Storms are mainly characterized by ENE waves associated with Bora (NE) winds or by SE waves when caused by Scirocco (SE) winds. Storm surge events predominantly occur during SE (Scirocco) winds, which coincides with the main SE–NW orientation of the Adriatic Sea. Bora storm waves are generally large and steep, whereas Scirocco waves are smaller in height but with a longer wave period due to the increased fetched of lower winds speeds across the Adriatic (Harley et al., 2016).

Several methods for storm characterization have been developed and implemented in recent years for the Mediterranean coast. Mendoza et al., (2011) proposed a five-class intensity scale, defining a storm as an event in which the significant wave height exceeds 1.5 m for at least 6 hours (Mendoza and Jiménez, 2006). Moving to a more local perspective, Armaroli et al. (2012) adopted the same physical definition of storm events for the northern Adriatic. Two storms are considered separated when the significant wave height decreases below the 1.5 m threshold for 3 or more consecutive hours. By analysing the events and their impacts together, Armaroli et al. (2012) classified a storm as “potentially damaging” when it exceeds the critical wave and total water level ($TWL = surge + tide$) threshold which are: $H_s \geq 2$ m and $TWL \geq 0.7$ m for urbanized beaches; $H_s \geq 3.3$ m and $TWL \geq 0.85$ m for natural beaches.
The pilot case study site is the portion of coast between Porto Garibaldi and Lido di Spina and is characterized by highly developed, low-lying sandy beaches, with touristic concessions (with concrete and/or wood buildings) directly facing the sea. The width of the beach ranges from ~20 m to ~150 m. The predominant sediment transport (longshore drift) is directed northward. The southern jetty of the canal harbour (Porto Canale) in Porto Garibaldi traps longshore sediment, resulting in widening of the beach at Lido degli Estensi and depleting the Porto Garibaldi beach. Erosion appears again in the southern part of Lido di Spina (Nordstrom et al., 2015), as shown in Figure 1D. The southernmost concession at Lido di Spina defines the southern boundary of the case study. In the whole area, the concessions can be affected by coastal storm impacts during extreme events (Nordstrom et al., 2015). The pilot case study presents areas that are well known at the regional level as coastal risk prone ones (Perini et al., 2016; Armaroli and Duo, 2017). The target area of the analysis of this pilot study, is the southernmost portion of the beach at Lido degli Estensi (Figure 1E) in the municipality of Comacchio, east of Ferrara and north of Ravenna.

**Figure 1. Field study site locations: A) Emilia-Romagna region; B) Coastal regional domain; C) Locations of the nearest tide gauge and wave buoy; D) Pilot case study site; E) Target area for data comparison.**

### 2.2 Coastal alerts and monitoring in Emilia-Romagna

The Emilia-Romagna Region (RER) developed a protocol for coastal storm alert and monitoring, within the framework of a wider system for hydro-geological risk alert, and several agencies and regional services are involved in the process (Ligorio et al., 2012). The daily forecasting of waves, surge and coastal impacts, provided by the Servizio IdroMeteoClima of the Agenzia Regionale per la Prevenzione, l'Ambiente e l'Energia (ARPAE-SIMC), are evaluated, along with the weather forecast, by the regional geological service (Servizio Geologico Sismico e dei Suoli, SGSS), the Centro Funzionale of ARPAE (ARPAE-CF), the regional Servizio Difesa del Suolo della Costa e Bonifica (SDSCB), the technical services (Servizi Tecnici di Bacino, STB), the inter-regional agency of the Po river (Agenzia Interregionale Fiume Po, AIPO) and the Civil Protection.

The forecasting of coastal hazards and impacts is provided through the Emilia-Romagna Early Warning System (E-R EWS), developed in the framework of the EU FP7 MICORE project (www.micore.eu), with the objective to predict the imminent arrival of a storm as a tool to be used by Civil Protection agencies and local communities (Ciavola et al., 2011; Harley et al., 2012, 2016; Jiménez et al., 2017). The E-R EWS is operational and is run by ARPAE-SIMC and the University of Ferrara (UNIFE) by executing a daily sequence of connected numerical models (COSMO, SWAN, ROMS, and XBeach) aiming at reproducing the hydro-morphodynamic response of the beach for 22 representative cross-shore profiles distributed along the regional coast. The final output of the chain is transformed into a format suitable for decision-makers and end-users (Harley et al., 2012). The EWS tool is based on Storm Impact Indicators (SIIs) (Ciavola et al., 2011) focusing on the magnitude of
water ingress and the type of exposed assets, which are described as natural or urbanized beaches (Harley et al., 2016). The daily outputs are published on-line at http://geo.regione.emilia-romagna.it/schede/ews/.

From 2017, the RER activated an on-line portal (https://allertameteo.regione.emilia-romagna.it/) where the alerts are published in a GIS-based interface. In case of forecasted over-threshold events, or unexpected ones, the alert is issued to the Civil Protection that forwards it to the local technical services and municipalities, at which point, the monitoring phase begins and updates are issued based on further observations (i.e. waves, water levels, wind, rains, etc.) and forecasting updates. If necessary, the emergency response is activated and implemented by the Civil Protection.

The SGSS oversees data collection and elaboration for coastal risk management purposes (Perini et al., 2015b; Armaroli and Duo, 2017). During and after a coastal event the geological service collects all available information from forecasting, observations, on-line pictures, webcam movies and news. After significant coastal events, the STBs are activated and implement on the ground surveys, documenting local impacts and measuring the water ingestion. The SGSS also survey (with DGPS techniques) 18 beach profiles in 13 locations along the coast, belonging to the regional beach monitoring network (Rete di Monitoraggio dei Profili di Spiaggia, REMPS). After an important event, the Civil Protection flies over the impacted areas taking oblique aerial pictures. However, this is not a regular procedure and is infrequently implemented. All the information is elaborated and archived by the SGSS in the public GIS-based coastal information system (Sistema Informativo del Mare e della Costa, SIC; http://ambiente.regione.emilia-romagna.it/geologia/temi/costa/sistema-informativo-del-mare-e-della-costasic), in the in_Risk and in_Storm platforms (Perini et al., 2015b).

The RER can be considered acting at the state-of-the-art in coastal alert and monitoring at the EU level (Perini et al., 2015b), as also publicly praised by the European Commission through a press release on the 26 September 2014 (http://europa.eu/rapid/press-release_IP-14-1046_en.htm).

2.3 Storm event

During the period 5-7 February 2015, an extreme (low-frequency and high-impact) storm hit the Emilia-Romagna coast and the whole of the Northern Adriatic Sea, causing extensive flooding of urban and natural areas. The storm occurred in the context of extreme regional weather conditions, which included heavy snow in the Apennines and rain in the alluvial plain of the Emilia-Romagna (ARPA E-R SIMC, 2015; Perini et al., 2015a, 2015b). The recorded water level was collected from the tide gauge of ISPRA (Istituto Superiore per la Protezione e la Ricerca Ambientale) located in Porto Corsini, Ravenna (Figure 1C). Wave data was recorded by the ARPA-ER (Agenzia Regionale per la Prevenzione e l’Ambiente dell’ Emilia-Romagna) offshore wave buoy located at 10 m depth, 5.5 km offshore from the town of Cesenatico (Figure 1C). The event, referred to by the colloquial name of the Saint Agatha storm, was identified following the Armaroli et al. (2012) storm definition. It began at night and lasted for 51 hours, making it one of the longest duration storms recorded by the local wave buoy offshore of Cesenatico (Figure 1C) since its deployment in May 2007. The maximum water level (surge + tide) of 1.20 m was measured at 23:40 GMT on 5 February. The non-tidal residual time-serie was assessed based on the tidal predictions (calculated for
Porto Corsini using data for the period 2007-2015 with t_tide; Pawlowicz et al., 2002) and showed a peak of 1.27 m in the morning of 6 February (Figure 2). The skew surge for the tidal cycle that included the peak of the total water level was calculated and resulted in 0.92 m. The significant wave height (4.6 m) and period (9.9 s) at the peak were recorded in the morning of 6 February (Figure 2). The wave direction was consistently from the ENE sector for the entire event duration.

According to the Mediterranean storm classification of Mendoza et al. (2011), the Saint Agatha storm is assigned to the severity class IV (“Severe”). The storm consequences were amplified by the combination of high waves, high water level, and intense rainfall that created combined problems to the local river discharge (Perini et al., 2015a, 2015b). Furthermore, according to the classification of Armaroli et al., (2012), the Saint Agatha storm was expected to have a strong impact on the coast, exceeding the combined wave and water level hazard thresholds (Figure 2).

Perini et al. (2015b) reported that the event was forecasted by the regional forecasting chain and the E-R EWS. An alert of Level 1 (out of 3 levels, from 1 to 3) was issued at regional level already on the 4 of February. The day after it was increased up to Level 2. The regional protocol allowed to monitor the evolution of the event with the support of measuring stations (i.e. weather, waves, water levels), webcams, waves and surge forecasts and the EWS alerts (updated every day). The monitoring of the damages started on the 6 of February: while the STBs were visiting the impacted locations from the ground, the Civil Protection implemented a first helicopter flight, providing oblique aerial pictures used later to map storm impacts. Two other flights were performed to complete the survey on the 8 and the 10 of February. In that period, the SGSS collected on-line material such as pictures, movies and news. All the information was archived in the regional database, although the material is currently not available online. However, information on the storm and its impacts are available at the RISC-KIT Storm Impact Database (http://risckit.cloudapp.net/risckit/#/) (Ciavola et al., 2017).

The whole dataset was used to evaluate the impacts along the coast and the observed ingress line (elaborated from aerial pictures and local measurements, where available) was compared with the risk maps produced for the Floods Directive (2007/60/EC) (Perini et al., 2016). Based on this analysis, Perini et al. (2015b) showed that the inundation extension was similar to the inundation scenario defined by an event with a representative return period of 100 years. In specific locations, however, the inundation exceeded the 100 years scenario limit, or, on the contrary, resulted more similar the 10 years flooding scenario.

Severe damages to several concession properties and urban areas were recorded along the coast (Perini et al., 2015a, 2015b). In the Ferrara province, the impacts were mainly confined to the exposed beach, causing significant damage to the concessions (urbanized beaches), to the dune systems (natural areas) and smaller harbours (e.g. flooding of the Porto Canale in Porto Garibaldi). In the Ravenna province, several coastal towns experienced extensive flooding of residential areas (e.g. Lido di Dante, Classe and Savio, where a flood water depth of 2 m was recorded; Perini et al., 2015b).

As part of the quick response effort, the research team performed post-event assessments at several locations in the Ferrara and Ravenna provinces within two weeks after the event. In this work, the analysis of the survey is presented for Lido degli Estensi (i.e. the target area in Figure 1E) in the Ferrara province is shown.
3 Methods

3.1 Quick Response Protocol

A local approach for coastal post-storm field surveys, hereafter called Quick Response Protocol (QRP), was developed and its application in the study area (Section 2) is hereafter presented. The approach was implemented by a team of surveyors, the Quick Response Team (QRT), by integrating E-R EWS input, RTK GPS and Unmanned Aerial Vehicle (UAV or drone) survey techniques, along with interviews with local stakeholders and damage observation. In the framework of the risk management cycle, the QRP is shown in its general form in Figure 3.

Ideally, the response must be activated as soon as possible, prior to recovery processes (natural or human-driven). In this study, the on-line regional forecasting system and the E-R EWS (see Section 2.2) provided guidance to the QRT by indicating the specific coastal areas within the regional domain that were likely to be impacted by the approaching storm and when conditions allowed for safe survey activities on-the-ground and in-the-air. Thus, the QRT knew prior to the storm impacting the coast where the quick response would most likely be needed and prepare in advance for personnel scheduling and survey equipment.

To detect morphological changes, a base-line of the pre-storm conditions needs to be defined. In general, the pre-storm survey, mainly a topo-bathimetric survey through both RTK GPS and UAV techniques, should be performed whenever possible, given enough time and resources. However, it is most critically necessary (i) in case studies where important morphological changes take place over short time-scales and/or (ii) when other sources of information are not available on the pre-storm condition in the likely impacted area. In all other cases, it is possible to assume that the base-line is represented by the most recent available topo-bathymetric dataset, accounting for the limitations linked to this kind of assumption, as it was done for this case study (see Section 3.2).

The implementation of the QRP included a number of field activities to acquire both qualitative and quantitative information on the storm in the immediate aftermath of the event. The critical tasks of the approach included the following activities:

- Conduct interviews of citizens, shopkeepers, restaurant owners, and other local stakeholders;
- Annotate the visible damage to coastal defences, buildings, infrastructures;
- Take pictures of the horizontal flood limits and vertical flood marks;
- Map and measure the vertical elevation of flood marks on buildings and defence structures;
- Map the horizontal flood limit;
Survey of the beach by means of RTK GPS (profiles and control points) and UAV flights.

In this application, the survey tasks focused on the emerged part of the beach as the UAV system was not capable of acquiring reliable information in the submerged area. In general, for micro-tidal environments, the RTK GPS technique can be used to survey the intertidal area of the cross-shore profiles. This information could be used in comparison with the pre-storm dataset, when covering the same area. However, this data would not be suitable to perform reliable 2D morphological analysis. Some possible improvements of this and other aspects are given in Section 6.

The QRP steps provided the necessary data to allow for an integrated analysis of the storm effects on the coast. The need to conduct rapid field survey activities in this study required the contribution of several people: at least 2 to 3 skilled operators were necessary to accomplish all the tasks in the field, every day. Depending on the alongshore extent and width of the coast that needs to be covered, the implementation of the protocol could last from a few days to a few weeks. In this study, 7 days were sufficient to complete the tasks along a total beach extent of almost 7 km for the case study site (Figure 1D), resulting in the integrated assessment rate of 1 km per day. In total, 10 profiles and more than 40 flood limits and flood marks were surveyed with RTK GPS technique. Six kilometers of beach were surveyed with the UAV and more than 50 GCPs (Ground Control Points) were surveyed on the ground with RTK GPS for use in the drone data processing, error analysis and data comparison.

The data processing and analysis of the acquired information is further described in the next sections, specifically focusing on the target area (Figure 1E). The integrated information will help to understand the overall effect of the storm in the surveyed area. The scientific aim of the QRP is to provide useful input to coastal managers for hazard and risk assessment purposes (Figure 3), integrating the post-storm information collected at the regional level.

**Figure 3. The Quick Response Protocol (QRP) in the framework of the Disaster Management Cycle.**

### 3.2 Pre-storm conditions

The pre-storm conditions of the subaerial beach and backshore were assumed to be represented by the available LiDAR-derived DTM from October 2014. The dataset was used as reference for the morphological variations of the emerged beach due to the storm impact, as no major events occurred between October 2014 and the Saint Agatha event.

### 3.3 Stakeholder interviews

Local stakeholders (SHs) were interviewed by the QRT on the morning of the 7 of February 2015. The interviews were mainly based on informal questions on the recent experience, focusing on the timing of the evolution of the flood event; what the people were doing before, during and after the event; if they were alerted and prepared. They were also requested to give an
interpretation of the causes of the impacts of the event. Ten SHs were interviewed in Porto Garibaldi (Figure 1D), the town in the north of Lido degli Estensi. The group included mainly owners of commercial or touristic services (e.g. concessions, restaurants, shops and others), a resident, a fisherman and a fireman. In this work, the interviews were mainly used to understand which local areas were mostly impacted, to better organize the field activities, and to understand the temporal evolution of the storm impacts.

3.4 RTK GPS survey

Field measurements relative to flood limits, flood marks, and beach profiles were taken using a RTK GPS (Trimble R6). All measurements were referenced to WGS84 UTM33N coordinates and the national geoid Italgeo99 for elevation. The flood limit denotes the maximum water progression on the plan view and it is evidenced by the presence of objects and debris moved inland by the water during the storm. It was associated with a GPS location (see Figure 4A). These points are hereafter called “GPS Floodlines”. A flood mark denotes the maximum water depth at a specific location where the water level was clearly visible, for example, walls, buildings, trees or dunes (e.g. Figure 4B). These points, hereafter called “GPS Floodmarks”, were associated with a GPS location and a measured water depth, e.g., with a simple meter (see Figure 4B). Cross-shore beach profiles were also surveyed to have a comparison (i.e. a posteriori) with the post-storm Digital Surface Model (DSM) generated from the UAV photogrammetric analysis (see Section 3.5). Ten cross-shore profiles were measured throughout the surveyed area highlighted in Figure 1D. The measurements were taken on the bare ground and thus excluding variation in the elevation due to debris, wood or others. Two profiles belong to the case study target area (Profile 1 and Profile 2 in Figure 1E). These profiles were used to provide a quantification of error (i.e. RMSE) of the UAV processed data.

Figure 4. Examples of “GPS Floodline” (A) and “GPS Floodmark” (B) measurements.

3.5 UAV survey and photogrammetric process

A commercial off-the-shelf UAV, the DJI Phantom Vision 2+, was used to conduct the aerial remote sensing imagery capture. The survey was performed with manual flight controls used to fly in a lawn-mower pattern (e.g. boustrophedon flight pattern) back and forth across the beach. Manual flights were performed as, at the time of the survey, the team did not have at its disposal automatic flight tools and software. This approach influenced the results (as expected) and this aspect will be emphasized and discussed in the following sections. Photos were automatically collected every three seconds from elevations between 40-60 m, at speeds of less than 4 m/s. The UAV camera utilized a fixed focal length and constant exposure. The resulting ground sampling distance and image overlap were estimated to be ~2.5 cm/pixel and ~70%, respectively. The UAV approach enabled surveying of the target area (~0.15 km²; Figure 1E) within a 10-minute flight collecting more than 550 images. Ground Control Points (GCPs) were measured using an RTK GPS (Trimble R6) for use within the photogrammetric
process. The GCPs were selected identifying objects on the beach (e.g. coloured plastic objects, wood or concrete platforms, etc.) that were considered easily detectable from the images. However, the resolution of the acquired images allowed detection of 14 GCPs for the target area (Figure 1E) that were used in the photogrammetric process.

A commercially available photogrammetry software package, specifically Pix4D Pro (Version 3.0.13), was used to stitch the collected UAV photos into one continuous orthomosaic by matching points within overlapping images utilizing Structure-from-Motion (SfM) algorithms. The application of UAV-based SfM photogrammetry for coastal morphology assessment has been recently demonstrated by the studies of Casella et al. (2014; 2016), Turner et al. (2016), Dohner et al. (2016) and Scarelli et al. (2017). The process followed the step-wise procedure illustrated in Figure 5. Images were initially matched using embedded GPS metadata from the UAV, characterized by poor accuracy (few meters). A sparse point cloud is created based on the identified matching points and the calculated initial image camera positions. Then, GCPs are manually identified on the pictures and their GPS information are used to reduce the error in georeferencing, as their position is measured with higher accuracy (few centimetres) than the images. A dense point cloud is therefore generated by densification of the corrected sparse cloud. The DSM and orthomosaics are then created from the dense point cloud. The dense cloud was not cleaned during the process, meaning that the points representing debris, wood or other objects were not removed and affected the final products.

This limitation, presented in other published works such as Casella et al. (2014), will be stressed and discussed in the following sections and specific remedies will be proposed in Section 6. The DSM and orthomosaic were then exported for the analysis (see Section 4). A summary of the information of the Pix4D report is given in Table 1 while, the distribution of the GCP vertical errors assessed by the photogrammetric software, is shown in Figure 1E.

Figure 5. Sequence of processing steps used in the photogrammetric workflow of UAV images. Main details of each step are given in the dashed boxes.
4 Results

The results of the post-event assessment are presented in the following. First, a summary of the interviews is given. Then, the results of the RTK GPS and UAV surveys are presented (and compared) for the target area (Figure 1E) of the pilot case study (Figure 1D).

4.1 Summary of the interviews

Many of the SHs reported that on the evening of the 5 of February (Thursday) the water level inside the Porto Canale of Porto Garibaldi (Figure 1D) was approaching the level of the embankments (~1.8 m above MSL) due to the combined effect of the canal discharge and the sea conditions. At that moment, the emerged beaches were already impacted by high water levels and waves. The overflow of the canal started between 01:00 and 02:00 GMT and continued till 04:00, mainly because of the oscillations of the water surface following wave propagation inside the canal. Early Friday morning, the situation was still critical, it only improved at lunch time, when the stormy sea conditions began to subside. Some of the SHs claimed that they did not remember a similar event in the last 30, 50 or even 60 years.

For the local people in Porto Garibaldi it was already clear on the 5 February 2015, that a strong coastal event was approaching their towns. However, several SHs claimed that no clear local alert to the population was given and none of those interviewed knew about the regional E-R EWS. Basically, local know-how and experiences were their only instruments to understanding and preparing for the situation (e.g. deploying sand bags). They also reported that the Civil Protection arrived at the location on the 6 of February (Friday), at approximately 13:00 GMT, bringing sand bags and assistance.

4.2 Elevation data

An indication of the quality of the DSM produced from the analysis of the UAV images is given comparing it with the RTK GPS cross-section points (see Figure 1E). The comparison is shown in Figure 6 for both profiles. For both datasets the assumed (i.e. a priori) vertical uncertainty is shown, namely ±15 cm for drone derived data and ±5 cm for RTK GPS data, illustrated by the shaded outlines. Outliers were deleted from the DSM data extracted for Profile 1 and 2 when they were visually determined to be clearly not representative of the terrain surface. However, it was not possible to correct the variations induced by debris or other small objects affecting the DSM in a similar manner and where therefore retained in the surface. Profiles were smoothed using a moving average for the DSM and RTK GPS derived data to reduce noise. The Root Mean Square Errors (RMSEs) of the vertical elevation between the RTK GPS and DSM data were 14 cm and 12 cm for Profiles 1 and 2, respectively. Note that Profile 2 is located in the central portion of the survey area, where more precision was expected due to greater image overlap and GCP control targets while, Profile 1 is closer to the edge of the domain where the DSM is expected to be less accurate. Since the DSM data comes from a commercial software and thus relies on GCPs for positioning accuracy, the UAV surveys are therefore not wholly independent of the GPS system. Nevertheless, the approach provide a useful and efficient dataset to integrate RTK GPS measurements.
This comparison aimed at giving an indication of accuracy and reliability of the resulting UAV-derived DSM which was corrected using the available GCPs. The DSM, while overestimating the elevation in the higher portion of the Profile 1, with the strongest difference on the order of 25-30 cm, converged with the RTK GPS profile in the lower portion of Profile 1 near the swash zone. For Profile 2, many of the morphological features were captured, including the storm berm (with a vertical error on the berm top of ~15 cm). The slopes of the emerged foreshore are comparable for both profiles: for Profile 1 the calculated slope was 0.016 for the UAV-derived profile, while it resulted in 0.014 for the RTK GPS profile. The same slopes calculated for Profile 2 resulted in 0.021 and 0.018, respectively. This profile convergence is implemented in further morphological change analysis as shown in Section 4.4.

Thus, the foreshore slope, berm shape, and berm crest locations are well captured by the UAV-derived DSM in Figure 6. The largest disagreement between the DSM and RTK GPS profiles occurs landward of the berm in the back portion of the beach (around 30 cm for Profile 1 and 20 cm for Profile 2). A combination of factors possibly contributed to this difference including lower sampling resolution of the RTK GPS compared to the UAV, the manual flight that does not allow for a full control on flight altitude and images overlap the inclusion of non-terrain elevations such as wood and debris in the DSM, and other affecting factors such as the texture of the beach surface and the position of the sun (see Sections 5 and 6 for the discussion of these limitations and proposed remedies, respectively).

Figure 6. Comparisons between the February 2015 post-storm observed RTK GPS profile survey and post-storm UAV-derived DSM for Profiles 1 and 2. The error bands, defined a priori (±15 cm for UAV and ±5 cm for GPS) for visualization purposes, are shown. The RMSE calculated a posteriori between the RTK GPS and UAV-derived data are reported.

4.3 Erosion and sedimentation patterns

The erosion and sedimentation patterns are shown in Figure 7. The morphological variations (Figure 7A1, B1 and C1) were obtained from the comparison between the DTM of October 2014 and the post-event UAV-derived DSM. The DSM included non-terrain objects and buildings, thus the analysis of the morphological features only focused on the emerged beach. The results are only presented for the area limited by the GCPs. The inclusion of non-beach features in the DSM, mainly because of the presence of different sized debris, affected the non-uniformity of the shown patterns.

Based on the results (Figure 7A1) a formation of a storm berm is clearly visible running alongshore with a varying width of 20 to 50 m. The vertical deposit is interrupted by erosion scour channels due to some return flows (Figure 7A1). Seaward of the depositional area (i.e. the storm berm) a negative variation pattern highlights the erosion of the ordinary berm, which intensifies just in front of the scour channels (Figure 7A1). Thus, the berm vertically grew and moved landward during the storm as result of sediment transport in the breaker zone (Figure 7A1). At the same time, a small portion of deposition in the intertidal area potentially corresponds to the development of a low tide terrace, just at the edge of the analyzed domain.
However, the domain does not include the lower intertidal area. Therefore, it is not possible to evaluate the morphological variation of the lower limit of the foreshore. A general lowering landward of the storm berm can be noted (Figure 7A1), which corresponds to the area where the differences between the RTK GPS profiles and the UAV-derived one were higher (see Section 4.2 and Figure 6). Thus, this variation can be subjected to error or even representing an artefact. Focusing on the selected frames (Figure 7B, B1, C, C1), visible scour channels are highlighted, that possibly developed from the footpaths thereby providing preferential pathways for water retreat seaward following storm conditions. This highlights the UAV’s ability to map finer resolution features such as scour channels.

Figure 7. Morphological variations: (A) the UAV-derived orthomosaic of the target area, where morphological features are visible along with the position of the GCPs; (A1) the difference between the post-event UAV-derived DSM and the pre-storm LiDAR-derived DTM. In B, B1 and C, C1 enlargements of the main features are given. The morphological variations are only shown for the area surrounded by the GCPs.

4.4 Coastal flooding

In Figure 8, the results obtained for the flood extent from the UAV-derived data are shown in comparison with the RTK GPS observed flood limits and marks. The orthomosaic was analyzed to extract the flood line by observing the debris that deposited on the beach (i.e. “Drone Floodline” in Figure 8). The high-resolution of the orthomosaic enabled the extraction of a detailed continuous flood extension, in comparison to the RTK GPS survey. Utilizing the orthomosaic, it was observed that several areas, that were not included in the main flooded areas, were reached by the water through small paths. Those spots, hereby defined “Drone Secondary Flood” areas, were identified and reported in Figure 8. An agreement is seen between the “Drone Floodline” and the RTK GPS derived flood line (“GPS Floodline”). As both depend upon the independent observation of objects and debris moved inland during the storm, the comparison can be considered as validation of the orthomosaic. The flooding was mainly limited to the beach in front of the concessions (Figure 8). Some of them, however, experienced secondary flooding where the limit of the flood reached the border of the concessions and the water found a path to flow in to the properties (Figure 8A, B, C, D). These impacts were also observed during the collection of picture and damage observation, but it was not possible to understand the extension of the flooding from the ground, as the private concessions were fenced and admission was not allowed. The maximum elevation reached by the water was calculated using the RTK GPS measurements (i.e. “GPS Floodline” and “GPS Floodmark” points) and extracting the elevation of the UAV-derived DSM along the “Drone Floodline”. The calculated average elevations reached by the water resulted in 1.634 m and 1.645 m for RTK GPS and UAV data, respectively. The associated standard deviations were 0.079 m and 0.196 m, respectively. The same analysis using the “Drone Floodline” was performed on the pre-storm DTM and it resulted in an average elevation of 1.663 m, with standard deviation equals to 0.093 m. A water depth of 30 cm was measured in the location of the flood mark (Figure 8A).
5 Discussion

In this section the results are discussed, along with their limitations, with focus on the summary of the local interviews and the comparisons between RTK GPS and UAV-derived data. A focus on the integration of the regional assessment with the local information is given.

The interviews to local SHs were useful at giving a picture of what happened during the night between the 5 and the 6 of February 2015 (see Section 4.1). The evolution of the event described by people was consistent with the observations. The interviews focused on the impacts in Porto Garibaldi mainly due to the overflow of the canal harbour. However, the interviewed could give indications on the impacted areas in the surroundings (i.e. Lido degli Estensi and Spina) and thus helping the research team at better organizing the field activities. An interesting aspect that was highlighted was that the population did not receive specific alerts. However, coastal managers reported that several alerts were issued before the event to municipalities and Civil Protection agencies (Perini et al., 2015b). The fact that the Civil Protection reached the location only on 6 of February (Friday), after the peak of the event, supports the hypothesis that, even if the alert was issued from the regional to the municipality level, there was a communication problem between the managers, the people in charge of responding to the emergency and the local population. This was also indirectly confirmed by the interviewed fireman who claimed that they were not even prepared to act on coastal locations. It also appeared that the population of the area was not aware of the on-line E-R EWS that they could have monitored. These aspects support the idea that more effort should be spent improving the preparedness and response of the Civil Protection and the awareness of the local population, especially by improving the communication channels and spreading the risk knowledge. These aspects were also reported by Martinez et al. (2017), about the same event and the same locations, in the wider framework of the aims of the EU FP7 RISC-KIT Project (GA 603458; www.risckit.eu) (Van Dongeren et al., 2017). Pescaroli and Magni (2015) also highlighted the importance of this aspects based on the analysis of interviews to local people in Cesenatico (Figure 1C). The limitations of the interviews here presented are mainly related to the lack of a standardized methodology, as the questions were mainly informal, and the limited number of people involved. A standard approach (e.g. using prepared questionnaire) can produce more reliable information that can be statistically analyzed, if the number of interviewed is large enough. Several examples of methodological approaches for stakeholder interviews and the analysis of their outcomes exist in the literature, for diverse purposes (Pescaroli and Magni, 2015; Becu et al., 2017; Gray et al., 2017; Martinez et al., 2017), that could be adapted to be applied during a post-storm assessment.
The RMSEs of 14 and 12 cm that were calculated between the processed DSM and the RTK GPS data (see Section 4.2 and Figure 6) are similar for both analyzed profiles and comparable with the LiDAR-derived data uncertainty. In comparison with error estimates of drone products reported by recent studies, the resulting RMSE values of the DSM compared to the traditional RTK GPS profile surveys are comparable (Casella, 2014 and 2016; Dohner et al., 2016) or higher (Turner et al., 2016; James et al., 2017; Scarelli et al., 2017). The low accuracy of the DSM product is attributed to aspects related to both the field implementation and the photogrammetric process. A recent study by James et al. (2017) provides practical suggestions to improve the quality of the field survey (e.g. modifications to drone flight characteristics, the number and spacing of GCPs, etc.). Overall DSM improvement is achieved through increased numbers of overlapping imagery, that can be properly controlled, for example, with automated flights that can also constrain the variability of the flight altitude. GCPs plays a major role on the quality of the photogrammetric products, being able to increase the accuracy of DSMs of one order of magnitude, when properly used (e.g. Moloney et al., 2017). In addition, the UAV-derived DSM should be considered valid in the area limited by the GCPs. The number, position and accuracy of the measured GCPs, that should be easily detectable from the images, are thus extremely important. In this application, the selected GCPs (i.e. objects found on the beach) were not always detectable from the images (because of the low resolution) and their distribution was not uniform, although conspicuous in number (14 GCPs for 0.15 km²). Following Seymour et al. (2017), it is possible to assume that the inaccuracy of the final product can be also due to the (combined effect of the) homogeneous texture of the beach surface and the high position of the sun during the flight (that in this study was performed at 12:00 GMT). Overexposure and smooth (in elevation and colour) surfaces can indeed undermine the SfM processing. Regarding the photogrammetric reconstruction, non-terrain objects (i.e. human structures and debris) were not removed or filtered from the point cloud during processing and remained in the dataset as was seen also in a similar storm response study by Casella et al. (2014). Thus, objects such as wood, litter and buildings, locally affected the represented surface. This, consequently, influenced the comparison with the post-storm RTK GPS observations, which only represented the terrain surface. The quality of the products can be further improved (see Section 6 for proposed improvements). However, the shown DSM was still able to capture key morphologic features (i.e. berm and scour channels).

The morphological patterns (see Section 4.3) derived from the drone data gave an opportunity to assess the morphological response of the beach at a detailed resolution. The results showed the erosion of the ordinary berm and the formation of a storm berm. The scouring channels highlighted in Figure 7 were potentially triggered by the presence of concrete pathways of local activities that concentrated and accelerated the return water flux during the storm. To reduce the formation of these scouring channels and the consequent worsening of beach erosion, a reasonable option would be to remove, or at least retreat landward, the pathways during the winter season (Nordstrom et al., 2015). The level of detail of the outcomes suggests that it is possible to use UAV-derived products to calculate volume variations, as already confirmed by the literature on the topic (e.g. Turner et al., 2016).

The UAV-derived orthomosaic offered a rapid way to map the flood extension (see Section 4.4). The general agreement with the RTK GPS on-the-ground observations confirmed the close geopositioning of the images and provided a validation of the
assessed flood extension. The opportunity to observe the flood extension from the UAV data made it possible to define a detailed and continuous flood line. To obtain the same results with a RTK GPS survey, the operator should increase the point sampling (or even use a continuous sampling method). This implies prolonging the field activities on the beach. Also, the aerial point of view is essential to have a complete view of the flood line evolution while, from the RTK GPS viewpoint, the random distribution and spreading of the debris can mislead the operator. The maximum elevations reached by the water, separately assessed considering RTK GPS measurements and the UAV-derived data, were comparable (~1.65 m), although the second one was characterized by higher uncertainty. As the maximum total water level measured during the storm was 1.20 m (P. Corsini tide gauge, Figure 1C; see Section 2.3), a component of ~0.45 due to wave run-up and set-up must be considered for the water to reach the estimated average elevations on the emerged beach. This value is comparable to the same component calculated using the formula proposed by Suarez et al. (2015) for storm conditions (i.e. 0.40 m and 0.53 m, respectively), considering the average slopes of 0.015 and 0.02 (which are representative of those calculated for the Profiles 1 and 2 analyzed in this study, see Section 4.1) and the hydrodynamics of the storm (see Section 2.3). On the other hand, it is lower than the component calculated with the traditional formula by Stockdon et al. (2006), which resulted in 1.14 m for both slopes (i.e. dissipative conditions).

When compared with the post-storm regional assessment reported in Perini et al. (2015b), the proposed survey approach for local assessments can produce very detailed and accurate data. Indeed, the flood ingression extracted from the dataset of Perini et al. (2015b) is not as accurate and detailed as the information that can be capture with drones flying at ~50 m height. Moreover, the regional analysis of the flood ingression was not implemented in this case study because the Civil Protection flight was performed too late, when the markers of the limit of the inundation were no longer identifiable from the helicopter (Armaroli C., personal communication). Thus, a direct comparison between the two observed flood extensions was not possible. However, the comparison of the regional flood maps (T10 and T100; Perini et al., 2016) with the "Drone Floodline" is shown in Figure 9, for the target area. In this location, the inundation extension was lower than the extension calculated for the 10 years return period event (T10). This is in contrast with the evidences of Perini et al. (2015b) at regional level and for the two reported examples of Lido di Savio and Cesenatico (see Section 2.3) that showed more similarity with the 100 years (T100) scenario. This difference can be attributed to the fact that the regional maps are calculated with a static approach, not grounded in process-based formulas or models, applying a constant total water level (1.49 m and 1.81 m for T10 and T100, respectively) at the shoreline and propagating the inundation with a modified bathtub-based approach over a 2 m resolution LiDAR DTM form 2008 (more details in Perini et al., 2016). Thus, site specific processes (e.g. wave run-up and set-up) are not properly considered, probably leading to the differences highlighted above. This hypothesis is also supported by the fact that the assessed maximum elevation reached by the water is close to the average between the levels used to calculate the T10 and T100 scenarios. Therefore, the observed flood line should have been located between the T10 and T100 flood limits.

Regarding the morphological analysis, the variations captured from the UAV can be used to calculate more accurate volume changes, at local level, than those that can be calculated on representative beach profiles along the coast. The regional approach indeed only focuses on a limited number of beach profiles along the coast. Moreover, the regional protocol does not include
any attempt to involve local people with interviews or other methods as the STBs, activated after the event, mainly collect qualitative information through direct observations and pictures (see Section 2.2).

Finally, the level of detail of the shown UAV-derived products as well as the efficiency of the field survey, make the presented approach very effective for the post-storm assessment when compared with pure RTK GPS or terrestrial laser scanner based approaches, as confirmed by the literature. For example, Moloney et al. (2017) estimated that to complete the survey (including set-up time) of the same area (i.e. a coastal dune test area of 85 m x 65 m) the RTK GPS technique required ~13.45 hours, the laser scanner ~3.66 hours, while the UAV only ~1.15 hours. The field efficiency of the UAV was also higher (10^4 and 25 times faster than the RTK GPS and laser scanner ones, respectively) in terms of rate of measured points per hours. Even considering that an RTK GPS survey can be completed by 1 skilled person, while the UAV needs 2-3 people like the laser scanner, the proposed approach results in more efficient and comprehensive data acquisition. Focusing on costs, while adopting low-cost UAVs, such as the one used in this study or in Moloney et al. (2017), and a licensed photogrammetric software, the RTK GPS survey method is less expensive. However, the higher costs of UAV-based surveys are balanced by the efficiency and the speed of the field activities.

In this sense, the proposed QRP can be very helpful at integrating and completing the regional protocol for post-storm assessment. As the regional authorities do not have sufficient manpower and instruments to perform such local detailed assessments along the whole coast, it is advisable to integrate local protocols (such as the QRP) in the regional one. The proposed approach can be performed at local level by academic and private survey teams (such as the QRT) that can be activated as STBs are (see Section 2.2), after the coastal event. The regional assessment, indeed, would benefit from the inclusion of more local, qualitative and quantitative information. By properly organizing the tasks assignments at different locations on the coast (i.e. the most impacted areas), it will be possible to activate a quick, coordinated protocol in the immediate aftermath of an event acting at regional and local level. This will provide more holistic data coverage, filling gaps and increasing the details and reliability of the assessments.

**Figure 9. Comparisons between the observed "DRONE Floodline" and the flood scenarios (T10 and T100) computed by Perini et al. (2016).**

6 Suggestions for possible improvements

In order to obtain high quality data, the following suggestions are given and should be implemented in the QRP.

The use of automatic flight planning can considerably improve the quality of the survey allowing the control of flight altitude and image overlap. The UAV survey should be planned on a larger domain (~10% buffer) than needed for data collection. Survey domain edge photos are often removed due to low overlap between images and data is lost.
The GCPs should be distributed throughout the survey domain and near boundaries to prevent skewing within the DSM product. As anticipated, the GCPs should be easily detectable as playing an important role in maximizing the accuracy of the photogrammetric products. This depends on both the quality of the images (that depends on the camera system, the type and altitude of the flight) and of the type of GCPs. An example of GCPs used during the survey can be found in Figure 10 with images of good (A, B) and poor (C, D) quality ones. Proper GCPs can be prepared using flat wood panels painted with two contrasting colours (e.g. red/white, yellow/black). In this case, however, the surveyors must bring them in the field while in this application the GCPs were selected using the objects found on the beach. On the ground, photos of GCP locations should be taken to have the idea of exactly where the RTK GPS point were taken on the target object and within the context of the survey domain.

As suggested in Section 5, environmental conditions (e.g. texture of the beach surface and sun conditions; Seymour et al., 2017) can influence the accuracy of the products and the operators should consider these aspects when planning the field activities.

The photogrammetric process can also be improved, for example, by spending more effort in cleaning and filtering the point cloud, thus minimizing the effect of debris and others on the final products.

As anticipated in the Section 3.1 the post-storm survey did not include the submerged area. To extend the protocol to this part of the beach, other innovative approaches should be adopted, such as near-shore low-cost autonomous surface systems (e.g. Hampson et al., 2011). However, it is beyond the aim of this work to include these aspects in the protocol.

Qualitative observations and interviews are also significant and should be performed as soon as possible and as detailed as possible during the implementation of the QRP. It is important to adopt standard approaches for stakeholder involvement and interview a large number of people in order to allow statistical analysis of qualitative information and increase representativeness.

The larger is the number of people involved for the post-event survey, the faster the data can be the collected. In addition, the team can be divide in groups with specific tasks (e.g. performing interviews, RTK GPS or UAV surveys, etc.), speeding up the survey process. Planning the activities is crucial for efficient and high-quality performance of the QRT. This can be additionally supported by activities completed during the non-storm season, such as instrument maintenance and preparation, monitoring of the warning system performances, tasks planning and assignment, etc.

To provide more accurate qualitative outcomes further analyses should be performed. This paper only presents the analysis of a small portion (Figure 1E) of the whole case study (Figure 1D) and deeper investigations (e.g. including forcing, sediment and volume change analysis, possibly supported by numerical models; including more detailed socio-economic aspects for precise impact assessments; etc.) are needed to provide more robust outcomes. However, the QRP has been demonstrated to be a proper approach to quickly assess the storm effects at local level in the immediate aftermath of an event, as a combination of technologies and planning approaches. Thus, in the framework of coastal management (Figure 3), a proper application of the protocol can produce useful information that can be used at local, regional and national levels in order to: (i) update hazard and risk maps; (ii) provide detailed information for flood-damage curves calibration (see, as example, the study of Scorzini
and Frank, 2017); and (iii) provide insights for risk mitigation and management plans. Finally, as suggested in Section 5, the QRP can be integrated in regional protocols, improving the reliability of the regional hazard and risk assessments.

**Figure 10.** Photos A and B at the top demonstrate practical GCPs based on unique shapes, colors, and ability to see from a high altitude. Photos C and D, on the bottom, demonstrate error-inducing GCPs due to their height off the ground and indistinguishable shape, size, and color in aerial images.

7 Conclusions

This case study illustrates the potentialities and benefits of an integrated approach combining Unmanned Aerial Vehicles (UAVs) together with on the ground Real-Time Kinematic Geographical Positions System (RTK GPS) surveys and qualitative data collection through stakeholders’ interviews for coastal storm impact assessments at local level. The presented protocol was applied at a pilot case study in the Emilia-Romagna coast, after the impact of an extreme coastal storm, and results were presented and discussed, for demonstration purposes, on a small portion of the pilot case study.

As a general remark, (i) interviewing local stakeholders and people in charge of emergency response tasks can be extremely useful at supporting the organization of the field activities, as well as at detecting lacks on the alert chain, preparedness and response emergency phases; (ii) the UAV approach was found to be effective for erosion and flooding assessments, being able to provide detailed, continuous and two(three)-dimensional information, with less time spent in the field in comparison with the traditional RTK GPS surveys and other approaches.

The main limitation of the analysis of the interviews was due to the lack of a standardized approach, that should be adopted (and adapted) from the literature. The main limitation of the drone products was linked to the field implementation and lacks in the photogrammetric process. Specific suggestions for improvements were given, such as the use of automated flights, proper GCPs and the cleaning of the point cloud during the photogrammetric process.

Regarding the proposed general approach, further applications can directly support hazard and impact assessment at local and regional level, and thus addressing coastal management needs. Indeed, the outcomes of the analysis were compared with the post-event assessment performed by the regional authorities highlighting that the proposed protocol for local assessment can be easily integrated in the regional ones, improving the details and reliability of the regional assessments.

In B, B1 and C, C1 enlargements of the main features are given. The morphological variations are only shown for the area surrounded by the GCPs.

Figure 8. Observed “GPS Floodline” and “GPS Floodmark” (green and red circles), UAV (red solid line and light-blue polygons) flood extension comparisons: the box on the left shows an overview of the target area while on the right (A, B, C and D) some spot-focuses are given.

Figure 9. Comparisons between the observed "DRONE Floodline" and the flood scenarios (T10 and T100) computed by Perini et al. (2016).

Figure 10. Photos A and B at the top demonstrate practical GCPs based on unique shapes, colors, and ability to see from a high altitude. Photos C and D, on the bottom, demonstrate error-inducing GCPs due to their height off the ground and indistinguishable shape, size, and color in aerial images.
